The ear is also involved in maintaining balance, and people with hearing loss may have balance problems. Body position, body movement, and balance are, in part, dependent on the vestibular apparatus of the inner ear, which consists of three functional parts. Two of these, the saccule and the utricle, signal the body position relative to gravity. The third structure consists of the three semicircular canals. These canals contain structures (ampullae) that detect movement of the internal fluid of the canals as the head moves. In most hearing-impaired people with balance problems, the semicircular canals do not function properly. Since the function of these canals is partially duplicated by the saccule and the utricle, most people can "learn" to use these other systems to compensate for dysfunction in the semicircular canals. Therefore, balance problems associated with hearing loss usually diminish over time.

A young boy signing the phrase "I love you" in American Sign Language to his baby brother. (Huntstock/Disability Images)

Syndromic hereditary hearing loss or deafness is associated with malformations of the external ear or other organs or with other genetic disorders affecting various organ systems. Nonsyndromic hereditary hearing loss or deafness is not associated with visible malformations of the external ear or other genetic disorders but can be associated with abnormalities of the middle or inner ear. Hereditary hearing loss and deafness are further classified as:

- prelingual (beginning before speech develops) or postlingual (beginning after speech develops)
- progressive (increasing over time) or nonprogressive (stable over time)
- bilateral (affecting both ears) or unilateral (affecting only one ear)
- symmetric (affecting both ears equally) or asymmetric (affecting each ear differently)
- conductive (resulting from abnormalities of the external ear or the ossicles of the middle ear with a normal auditory nerve), sensorineural (dysfunction of the inner ear or auditory nerve), a combination of the two types (mixed hearing loss), or central auditory dysfunction in the auditory brainstem or auditory regions of the brain
- severity from mild to profound as measured in decibels (dB)

Syndromic hearing loss

Syndromic hearing loss accounts for approximately 30% of hereditary hearing loss and deafness. Some of the more common genetic disorders associated with hearing loss include Waardenburg syndrome, Usher syndrome, Jervell and Lange-Nielsen syndrome, and Alport syndrome. In Waardenburg syndrome, hearing loss occurs in conjunction with pigmentation abnormalities of the skin,

eyes, and hair. In Usher syndrome, hearing loss is associated with eye abnormalities that progress to blindness. In Jervell and Lange-Nielsen syndrome, hearing loss is associated with heart abnormalities. In Alport syndrome, hearing loss is associated with kidney abnormalities.

Nonsyndromic hearing loss

Nonsyndromic hearing loss accounts for approximately 70% of hereditary hearing loss and deafness. Nonsyndromic prelingual hearing loss is most frequently sensorineural and inherited in an autosomal recessive pattern.

Otosclerosis is the most common form of nonsyndromic progressive conductive hearing loss in adults. It is caused by the growth of spongy bone tissue in the middle ear that prevents the ossicles (malleus, incus, stapes) from moving freely. In advanced cases of otosclerosis, there may also be damage to the auditory nerve (sensorineural hearing loss). Otosclerosis can occur in teenagers, but it is generally first observed in people between the ages of 20 and 50. It is very rare past the age of 50.

Dominant progressive hearing loss (DPHL) and presbycusis (hearing loss related to aging) are the most common forms of nonsyndromic progressive sensorineural hearing loss. Presbycusis is not believed to have a genetic basis. DPHL tends to have an earlier age of onset than presbycusis, but this varies greatly among affected families. Within families, the age of DPHL onset is generally fairly constant, most often beginning in early childhood, although in some families symptoms do not occur until early or middle adulthood. Some individuals with DPHL also have problems with balance because of an alteration of the semicircular canal structures within their inner ears. Balance problems are not observed in all cases of DPHL, suggesting that DPHL may be caused by more than one gene mutation.

Genetic profile

More than 100 different genes have been associated with hereditary hearing loss and deafness, and it is expected that more associated genes will be identified in the future. Furthermore, different changes (mutations) in the same genes can cause either syndromic or nonsyndromic hearing loss. Hearing loss and deafness can be inherited in different patterns: autosomal dominant inheritance, autosomal recessive inheritance, X-linked inheritance, and mitochondrial inheritance.

Individuals with an autosomal dominant form of hereditary hearing loss have a 50% chance of passing on the gene for hearing loss in each pregnancy, regardless of the gender of the parent or child. Most people with this

type of hereditary hearing loss have an affected parent; however, autosomal dominant hearing loss can occur as a new sporadic mutation in an individual with no family history. If the new mutation affects the person's germline (egg or sperm cells), there is a 50% chance of passing on the hearing loss to each child.

Individuals with an autosomal recessive form of hereditary hearing loss have inherited mutated genes from both their mother and their father. Most people with autosomal recessive hereditary hearing loss do not have affected parents; in most cases, the parents carry silent genes for hearing loss that never caused problems.

Individuals with X-linked hearing loss have inherited a gene for hearing loss located on the X chromosome. Females have two X chromosomes, whereas males have one X and one Y chromosome. Therefore, the vast majority of people affected by X-linked recessive hereditary hearing loss are male. Females may be carriers, but they are rarely affected. However, in the case of an X-linked dominant hearing loss gene, all of the daughters of an affected father will have hearing loss, because they have all inherited their father's X chromosome.

While most genetic information is carried on the chromosomes in the nucleus of the cell, there is also a small amount of DNA in the mitochondria of cells. Mitochondria are inherited from the mother. The percentage of hereditary hearing loss due to abnormalities in mitochondrial DNA is estimated to be about 1%. Hearing loss due to mitochondrial inheritance shows highly variable penetrance (the degree to which the hearing loss gene is expressed).

Syndromic hearing loss and deafness

AUTOSOMAL DOMINANT. Waardenburg syndrome is the most common autosomal dominant form of syndromic hereditary hearing loss. Even within a single family, however, symptoms vary. Affected family members may have white patches of skin or hair, differently colored and widely spaced eyes, and/or varying degrees of sensorineural hearing loss. Waardenburg syndrome types I and III are caused by mutations in the *PAX3* gene. Some cases of Waardenburg syndrome type II are associated with mutations in the *MITF* gene. Waardenburg syndrome type IV has been associated with mutations in three genes: *EDNRB*, *EDN3*, and *SOX10*.

The second most common autosomal dominant form of syndromic hereditary hearing loss is branchiootorenal (BOR) syndrome. Symptoms vary even within families. Affected people may have sensorineural, conductive, or mixed-type hearing loss, along with abnormalities of the external ear, cysts on the neck, and/or kidney problems. Mutations in the *EYA1* gene located on chromosome 8

have been found in about 40% of families with BOR syndrome. Still other families with BOR syndrome show mutations in the *SIX1* gene on chromosome 14. Other genes responsible for BOR syndrome have not yet been identified.

Stickler syndrome includes progressive sensorineural hearing loss. Mutations in the *COL2A1* and *COL11A1* genes cause severe nearsightedness as well as hearing loss. Mutations in *COL11A2* cause hearing loss without vision problems.

Neurofibromatosis 2, caused by mutations in the *NF2* gene that results in nerve cell tumors, is associated with a rare but potentially treatable form of deafness that begins in the third decade of life.

AUTOSOMAL RECESSIVE. The most common type of autosomal recessive syndromic hearing loss is Usher syndrome. Infants with Usher syndrome are born with severe sensorineural hearing loss. They later develop retinitis pigmentosa—degeneration of the retina, the light sensitive layer of tissue at the back of the inner eye. This leads to visual problems and sometimes total blindness. Usher syndrome is the cause of more than 50% of combined deafness and blindness in the United States and is estimated to account for 3%–6% of all congenital deafness. Usher syndrome has been divided into three types based on the severity of symptoms. The more severe type I is characterized by congenital severe-to-profound hearing loss, vestibular dysfunction, and retinal degeneration beginning in childhood. Usher syndrome type I can be caused by mutations in the *USH1B*, *USH1C*, *USH1D*, *USH1F*, or *USH1G* genes. The moderate Usher syndrome type II is characterized by congenital mild-to-severe hearing loss, normal vestibular function, and later onset of retinitis pigmentosa. Usher syndrome type II has been localized to three different chromosomal regions, and mutations in the *USH2A* gene have been associated with type II. The milder Usher syndrome type III is characterized by progressive hearing loss. Usher syndrome type III has been localized to the long arm of chromosome 3.

Pendred syndrome is the second most common type of autosomal recessive syndromic hearing loss. It is characterized by severe-to-profound congenital sensorineural hearing loss due to an abnormality in the bony labyrinth of the ear. Goiter, an enlarged thyroid gland, develops in puberty or adulthood. About half of Pendred syndrome-affected families carry pathogenic variants in the *SLC26A4* gene. Mutations in *SLC26A4* can also cause nonsyndromic hearing loss (DFNB4).

Jervell and Lange-Nielsen syndrome is the third most common type of autosomal recessive syndromic hearing loss. It is characterized by congenital deafness and a heart

abnormality called long QT syndrome. Pathogenic variants in two different genes have been associated with this syndrome.

X-LINKED. Alport syndrome is an example of X-linked syndromic hearing loss. Males with Alport syndrome have progressive kidney problems that lead to kidney failure and early death. Many males with X-linked Alport syndrome develop progressive sensorineural hearing loss beginning after age 10. They may also have an abnormality in the shape of the lens called anterior lenticonus. Females with X-linked Alport syndrome may have kidney problems and deafness but usually with a later onset and less rapid progression. Alport syndrome may be autosomal dominant or autosomal recessive as well as X-linked, but about 85% of cases show X-linked inheritance. About 15% are autosomal recessive. Autosomal dominant inheritance appears to be very rare.

MITOCHONDRIAL. Syndromic mitochondrial hearing loss is more common than nonsyndromic mitochondrial hearing loss due to the functioning of the mitochondria. Because mitochondria are responsible for energy production, faulty mitochondria result in decreased energy production. This lower level of energy production greatly affects the parts of the body that use the most energy, including the brain, heart, and muscles. Therefore, people with mitochondrial disorders generally have a spectrum of physical symptoms, including nervous system problems, visual problems, hearing loss, and muscle weakness. MELAS, MERRF, and Kearns-Sayre syndromes are mitochondrial syndromes that include hearing loss. More than half of people with diabetes mellitus and a specific mutation in the mitochondrial *MTTL1* gene in Japan have been found to have sensorineural hearing loss that develops after the onset of diabetes. This mutation is also associated with MELAS.

NONSYNDROMIC HEARING LOSS AND DEAFNESS. Most cases of hereditary hearing loss are nonsyndromic and autosomal recessive. Most autosomal recessive hearing loss is prelingual and severe-to-profound. Most autosomal dominant hearing loss is postlingual. Approximately 75%–80% of nonsyndromic prelingual hereditary hearing losses are due to autosomal recessive mutations, and about 20% are due to autosomal dominant mutations. The rare remaining cases of nonsyndromic hereditary hearing loss are attributed to X-linked and mitochondrial disorders (about 1% each). The gene loci associated with nonsyndromic deafness are designated DFN for “DeaF-Ness.”

- DFNA are autosomal dominant.
- DFNB are autosomal recessive.
- DFNX are X-linked.

Mutations in the *GJB2* gene that encodes the protein connexin 26 or the *GJB6* gene that encodes connexin 30 cause DFNB1 and account for 50% of all autosomal recessive nonsyndromic hearing loss, including 30% of hearing losses with no family history. It is estimated that at least 3% of people with normal hearing carry a silent mutation in one of their *GJB2* genes. If a mother and father each are unaffected carriers of a mutation in *GJB2*, each of their offspring has a 25% risk of inheriting hearing loss.

No single gene has been identified as responsible for most autosomal dominant nonsyndromic cases of hearing loss. However, many genes have been associated with nonsyndromic hearing loss and deafness, and different mutations in the same gene can cause different types of hearing loss.

- Different mutations in the *TECTA* gene that encodes the alpha-tectorin protein can cause either DFNA8/12 or DFNB21, depending on the location of the mutation in the gene.
- Mutations in the *GJB2* and *GJB6* gene can cause DFNA3 or DFNB1.
- Mutations in *MYO7A* can cause DFNA11 or DFNB2 as well as Usher syndrome type 1B.
- Mutations in *USH1C* can cause DFNB18 as well as Usher syndrome 1C.
- Mutations in *CDH23* can cause DFNB12 or Usher syndrome 1D.
- Mutations in *SLC26A4* can cause DFNB4 or Pendred syndrome.
- Mutations in *WFS1* can cause DFNA6/14/38 or Wolfram syndrome.

Otosclerosis is inherited in an autosomal dominant pattern but has reduced penetrance. A dominant condition with complete (100%) penetrance affects all individuals with the single gene mutation. However, many individuals with a genetic mutation known to cause otosclerosis do not have any symptoms of hearing loss. Furthermore, because otosclerosis can have a late onset, family members die before showing signs of hearing loss.

Several chromosomal locations are associated with nonsyndromic X-linked deafness (DFNX). DFNX3 is caused by mutations in the *POU3F4* gene located on the long arm of the X chromosome. People with mutations in this gene have mixed-type hearing loss. The conductive portion of their hearing loss is caused by abnormal attachment of the stapes.

Nonsyndromic mitochondrial hearing loss is associated with mutations in either the mitochondrial *MTRNR1* gene or the mitochondrial *MTTS1* gene. Nonsyndromic

KEY TERMS

Autosomal dominant—A pattern of genetic inheritance in which only one abnormal gene is needed to express the trait or disease.

Autosomal recessive—A pattern of genetic inheritance in which two abnormal genes are needed to express the trait or disease.

Branchiootorenal (BOR) syndrome—The second most common autosomal dominant form of syndromic hereditary hearing loss.

Cochlea—The spiral-shaped, fluid-filled hearing apparatus of the inner ear.

Conductive hearing loss—A blockage of sound vibrations from the eardrum to the inner ear due to a problem in the outer or middle ear.

Decibel (dB)—A logarithmic unit for expressing loudness or intensity; normal speech is typically in the range of 20–50 dB.

Dominant progressive hearing loss (DPHL)—The most common type of hereditary nonsyndromic progressive sensorineural hearing loss.

Hearing level (HL)—Hearing threshold; the sound level that can just barely be heard.

Mitochondrial inheritance—Genes located within the mitochondria of cells that are inherited from the mother.

Nonsyndromic hearing loss—Hereditary hearing loss that is not part of another underlying genetic disorder.

Ossicles—The three tiny bones in the middle ear

Otosclerosis—Growth of spongy bone in the inner ear that causes progressive hearing loss and deafness.

Pathogenic variant—A mutation or variation in a gene that causes a genetic disorder.

Sensorineural hearing loss—Hearing loss caused by an abnormality in or permanent damage to the inner ear, the auditory nerve, or the auditory center of the brain.

Syndromic hearing loss—Hearing loss that occurs as part of an underlying genetic syndrome.

Usher syndrome—The most common type of autosomal recessive syndromic hearing loss.

Waardenburg syndrome—The most common autosomal dominant form of syndromic hearing loss.

X-linked—A gene located on the X sex chromosome.

mitochondrial hearing loss varies from moderate to profound. One specific mutation in *MTRNR1* has been reported both in families with nonsyndromic hearing loss and in families with hearing loss induced by exposure to aminoglycoside antibiotics. People with this mutation develop hearing loss within a few days to weeks of taking the medication; without exposure to the antibiotic, hearing loss develops at a median age of 20 years. Hearing loss caused by *MTTS1* mutations often develops in childhood.

Demographics

It is estimated that approximately 10% of the population of the United States has hearing loss or deafness. This number is higher worldwide because many nongenetic causes of hearing loss are more prevalent outside of the United States. Congenital hearing loss is estimated to affect 2 to 3 out of every 1,000 babies born in the United States. It is estimated that approximately 50% of childhood hearing impairment in the United States is genetically based. Another 20%–25% of cases are attributed to environmental factors. The remaining 25%–30% of cases are of unknown cause. The incidence of hearing loss increases with age. Approximately 17 out of 1,000 children under age 18—but 40%–50% of people over 75

—have hearing loss. This age-related increase reflects the interaction of genetic susceptibility and environmental triggers.

Approximately 85%–90% of deaf individuals intermarry, but 90% of deaf couples have children with normal hearing, and 90%–95% of deaf children have parents with normal hearing. In general, if a hearing couple has a child with profound deafness of unknown cause, their risk of having another child with hearing loss is one in six for each future pregnancy.

Otosclerosis is estimated to affect between 10% and 18% of all white and Hispanic women and between 7% and 9% of all white and Hispanic men. People of Asian descent are affected with otosclerosis at about half the rate of whites and Hispanics, with the same observed sex differences. Only about 1% of African Americans are affected by otosclerosis, with minimal differences between males and females. Otosclerosis is exceedingly rare in people of Native American descent.

Signs and symptoms

Syndromic types of hearing loss generally have signs and symptoms associated with the particular syndrome.

QUESTIONS TO ASK YOUR DOCTOR

- Is my hearing loss inherited?
- Is my hearing loss conductive or sensorineural?
- Is my hearing loss part of a genetic syndrome?
- Is genetic testing available for my type of hearing loss?
- Is my hearing loss progressive?

Otosclerosis is characterized by an initial loss of hearing in the low frequencies, followed by a loss of the high frequencies, then a loss of the middle frequencies. It may rapidly advance through these stages or stabilize for a period of years before progressively worsening. Many affected individuals have symptoms only in one ear at first, but otosclerosis almost inevitably eventually affects both ears. The maximum hearing loss due to otosclerosis without involvement of the auditory nerve is in the moderate range. As an affected person ages and the auditory nerve becomes involved, hearing loss may progress to severe or even profound.

There are four main categories of DPHL: early-onset, high-frequency, mid-frequency, and low-frequency. Early-onset types of DPHL tend to occur in early childhood and progress at varying rates to deafness. The other three types are categorized by the frequency range in which hearing loss first occurs.

Hearing loss is categorized by the hearing threshold. Hearing threshold is the level of sound that can just barely be heard. The hearing threshold of an individual is the hearing level (HL) of that person. It is measured in decibels (dB). Normal hearing is up to a 25-dB HL. Mild hearing loss is defined as an HL in the 26- to 45-dB range. Moderate hearing loss is defined as an HL in the 46- to 65-dB range. Severe hearing loss is defined as an HL in the 66- to 85-dB range. Profound hearing loss is defined as an HL greater than 85 dB. The average person speaking English in a conversational tone tends to speak in the 30- to 60-dB range, depending on the particular sounds. People with mild hearing loss are generally able to hear and understand one-on-one conversations if they are close to the speaker, but they may have difficulty hearing a speaker who is far away, has a soft voice, or is surrounded by background noise. People with moderate hearing loss may have problems hearing conversational speech, even at relatively close range and in the absence of background noise. People with severe hearing loss have difficulty hearing in most situations, unless the

speaker is talking loudly and is at relatively close range. People with profound hearing loss may not hear loud speech or environmental sounds. These people are unlikely to use hearing and speech as primary means of communication.

Hearing loss is also measured in terms of the frequency (hertz) of the sounds that can be heard. The normal hearing range for humans is approximately 100–8,000 hertz (Hz). The normal frequency of sounds in the English language falls between approximately 240 Hz and 7,500 Hz. In individuals with progressive conductive hearing loss, it is generally the highest frequency range or the lowest frequency range that is lost first; the middle-frequency range is generally lost last. In individuals affected with progressive sensorineural hearing loss, any of the three frequency ranges may be lost first. Hearing loss is generally plotted on a graph called an audiogram. This is a graph of frequency (in Hz) versus HL (in dB).

Diagnosis

Genetic forms of hearing loss are diagnosed by an ear (otologic) exam, hearing tests (audiometry), a physical exam, family history, imaging studies such as computed tomography (CT) of the temporal bone, and molecular genetic testing. Genetic testing is available for many types of syndromic and nonsyndromic hearing loss and deafness. Prenatal testing may also be available.

Syndromic hereditary hearing loss is usually diagnosed by other signs of the particular syndrome. Types of nonsyndromic hereditary hearing loss may be diagnosed by the age of onset, degree of progressiveness, degree of symmetry between the two ears, and the type of hearing loss—conductive, sensorineural, or mixed.

Hearing is generally tested using earphones. Sounds are sent into the earphones at various decibel and frequency levels to determine the amount of hearing loss in dB and the range of hearing loss in Hz. Since hearing loss is not necessarily the same in both ears, each ear is tested independently. Another test is performed to determine whether hearing loss is conductive or sensorineural. A device called a bone vibrator is used in place of the earphones. The bone vibrator sends auditory signals through the bones of the ear, bypassing the ear canal and the ossicles of the middle ear. In the case of conductive hearing loss, the affected individual will be able to hear sounds at a lower decibel level using the bone vibrator than using the earphones. In the case of sensorineural hearing loss, the affected individual will generally hear sounds through the bone vibrator at the same decibel level as with the earphones.

Other diagnostic tests include:

- auditory brainstem response testing to evoke responses in the auditory nerve and brainstem
- auditory steady-state testing
- evoked otoacoustic emissions to determine the activity of the outer hair cells of the cochlea
- acoustic immittance testing to assess the peripheral auditory system, including middle-ear pressure
- various specialized types of audiometry

Newborn screening for congenital hearing loss is required in many states and offered to all in most other states.

Treatment and management

Certain types of conductive hearing loss can be treated by surgery to correct the dysfunctional portion of the ear. Sensorineural hearing loss is generally not surgically repairable. Children over 12 months with severe-to-profound hearing loss may be candidates for cochlear implants.

Most people with partial hearing loss can benefit from the use of hearing aids and/or sign language. Sign language and writing are often the primary forms of communication used by people who have severe or profound hearing loss or total deafness.

Prognosis

The prognosis for individuals affected with hereditary hearing loss is largely dependent on the type of hearing loss and the presence of additional symptoms in syndromic types. Hearing aids and/or sign language can greatly improve the quality of life for people affected by hereditary hearing loss and deafness.

Hereditary hemorrhagic telangiectasia

Definition

Hereditary hemorrhagic telangiectasia (HHT) is a disorder of the blood vessels, typically involving recurrent nosebleeds (epistaxis) and telangiectases (small malformations that result in small red spots on the skin) of the lips, mouth, fingers, and nose. Arteriovenous malformations (AVMs) are abnormal direct connections between the arteries and veins (blood vessels), causing abnormalities in blood flow. AVMs are often present in HHT and may occur in the lungs, stomach, liver, or brain. HHT was formerly known as Osler-Weber-Rendu (OWR) syndrome and is still called by that name by some physicians.

Description

HHT was first described in the late nineteenth and early twentieth centuries by several physicians, most notably the Canadian, Sir William Osler, who showed that HHT runs in families; the Englishman, F. Parkes Weber, who published a notable case series; and the Frenchman, Henri Jules Louis Marie Rendu, who distinguished HHT from hemophilia. The present preferred name, hereditary hemorrhagic telangiectasia, was introduced by an American physician, Frederick R. Haines, in 1909.

Close-up of the face of a patient affected by hereditary hemorrhagic telangiectasia. In this condition, telangiectases (collections of distended blood capillaries) develop on the skin and mucous surfaces. (P. Marazziti Science Source)

HHT is caused by genetic defects that affect angiogenesis, the process in which new blood vessels are formed out of preexisting ones. Because of these defects, abnormalities in the structure of the blood vessels lead to small vascular malformations known as telangiectases and larger ones known as arteriovenous malformations (AVMs) in various parts of the body. Telangiectases are most commonly found near the surface of the skin of the lips, nose, fingers, and face; in the mucous membranes lining the nasal passages; and in the tissues lining the digestive tract. Telangiectases are prone to recurrent bleeding, which explains why one of the most common symptoms of HHT is epistaxis, or nosebleeds.

The larger AVMs are usually found in the lungs, liver, or brain, with a very few occurring in the spinal cord, and may lead to more serious loss of blood and other health problems. AVMs in the brain itself may cause headaches. AVMs in the lungs may bypass the capillaries that normally filter out blood clots; the blood clots may then migrate to the brain and cause stroke.

It is very rare for an individual to have all the symptoms associated with HHT or to have them with equal severity. In addition, the time of symptom onset varies from patient to patient. Some patients develop symptoms in infancy, others in early childhood. However, puberty is the most common time for the onset of nosebleeds. Bleeding in the digestive tract is most likely to appear in adults in their 30s or 40s. The differences in symptom location, severity, and time of onset are related to the different genetic mutations linked to HHT.

People with HHT do not have any mental limitations and therefore have the same academic potential as anyone else. Children with HHT may develop anemia, however,

and may find it difficult to keep up the same level of activity as their peers.

Genetic profile

HHT is known to be characterized by genetic heterogeneity. Mutations in at least five different genes (two as yet unidentified) are known to cause HHT; it is highly likely that more genes linked to the condition will be discovered in the future. HHT is presently divided into five subtypes according to the genetic mutations that cause them:

- **Type 1:** HHT type 1 is caused by mutations in the *ENG* gene on the long arm of chromosome 9 at 9q34.1. Patients with type 1 HHT typically develop symptoms earlier than those with type 2 and are more likely to develop AVMs in the lungs and brain.
- **Type 2:** Type 2 HHT is caused by mutations in the *ACVRL1* gene on the long arm of chromosome 12 at 12q11-q14. Patients with type 2 HHT are usually older when their symptoms first develop and are more likely to develop AVMs in the liver. Types 1 and 2 taken together account for about 80% of cases of HHT.
- **Type 3:** Type 3 is caused by mutations in an unknown gene mapped to the long arm of chromosome 5 at 5q31.3-q32. Patients with type 3 HHT are also more likely to develop AVMs in the liver.
- **Type 4:** Type 4 HHT is caused by mutations in an unknown gene mapped to the short arm of chromosome 7 at 7p14. Types 3 and 4 are relatively rare.
- **Type 5:** Type 5 HHT is caused by mutations in the *MADH4* gene (also called the *SMAD4* gene) on the long arm of chromosome 18 at 18q21.2. Type 5 HHT is also known as juvenile polyposis hereditary hemorrhagic telangiectasia syndrome, or JPHT, because patients develop multiple polyps in the lining of the digestive tract at an early age, which increases their risk of cancer in addition to the other symptoms of HHT. This type accounts for only 2% of cases of HHT.

All five types of HHT are inherited in an autosomal dominant pattern, which means that only one copy of the defective gene is needed for the disorder to appear in an individual. The role that these specific genes play in the pathogenesis of HHT, however, is not fully understood. All the genes presently linked to HHT code for a family of signaling proteins known as TGF-beta/BMP, which affect such functions as cell survival, reproduction, and specialization (differentiation). It is thought that mutations in these genes interfere with cell signaling during the process of angiogenesis, leading to malformed blood vessels that are fragile and easily broken (friable). Over 600 different mutations in the HHT-associated genes had been identified as of 2015.

Demographics

HHT is believed to affect about 1 in every 5,000 people in most parts of Europe and Japan; it is less common in the United States, with one or two cases reported each year per 100,000 people—which likely reflects underdiagnosis. The exception for the United States is Vermont, with a reported incidence of 1 case per 16,500 residents.

HHT is found worldwide, but a higher prevalence exists in the Danish island of Funen (1 case per 3,500 people), the Dutch Antilles, and parts of France (1 case per 8,345 people). All types of HHT affect both males and females.

Signs and symptoms

The symptoms of HHT result from several AVMs, which may occur in differing severity and areas of the body. Ultimately, AVMs may lead to mild or severe bleeding in affected areas. About 90% of people with HHT experience frequent nosebleeds. These occur because the layers of mucous membranes in the nose are very sensitive and fragile, and telangiectases in this area can easily bleed spontaneously. Recurrent nosebleeds may begin by about 12 years of age and are not always severe enough to result in medical treatment or consultation. Occasionally, severe nosebleeds can cause mild to severe anemia, sometimes requiring a blood transfusion or iron replacement therapy.

Telangiectases commonly occur on the nose, lips, tongue, mouth, and fingers. They may vary in size from a pinpoint to the size of a small pea. Because telangiectases are fragile, sudden bleeding may occur from only a slight trauma, and bleeding may not stop by itself. Thirty percent of people with HHT report telangiectases first appearing before age 20, and 67% before age 40. Telangiectases and larger AVMs can be found anywhere in the gastrointestinal system, and if large enough they may cause a significant amount of internal bleeding. This bleeding may become more severe with age but usually does not appear until age 40.

Pulmonary AVMs (AVMs in the lung) may cause bleeding within the lungs. These are problematic because the abnormal connections between arteries and veins bypass the natural filtering system within the lung, allowing bacteria to enter the system. Low levels of oxygen and infection may result, causing migraine-like headaches. An individual with a pulmonary AVM may experience intolerance to exercise or may have areas of his or her skin turn blue (cyanosis, due to low oxygen levels). Complications in the brain may also result, sometimes causing stroke. Occasionally, AVMs may occur in the spine, liver, and brain. An AVM in the liver can cause blood to be drawn away from the normal circulation, increasing the

risk of heart failure because the heart must work harder to compensate for the large amounts of blood withdrawn from the rest of the body by the AVM in the liver.

Diagnosis

As of 2015, the clinical diagnosis of HHT was based on four criteria established by the scientific advisory board of the HHT Foundation International in 1999. The so-called Curaçao criteria are as follows:

- presence of epistaxis
- presence of telangiectases
- AVMs in the internal organs
- a first-degree relative (parent, child, or sibling) with HHT

A diagnosis of HHT is considered definite if the patient meets three or all four of the four criteria; possible or suspected if two are met; and unlikely if fewer than two are met.

In spite of the widespread use of the Curaçao criteria, HHT is difficult to diagnose (and is often underdiagnosed) because bleeding and venous malformations may occur in otherwise healthy individuals. For example, isolated nosebleeds are very common in the general population and may occur for a variety of reasons. Because nosebleeds are often the first sign in HHT, they may initially be ignored until they become so frequent that they are brought to medical attention. Isolated internal bleeding is quite common in the brain and GI tract. However, not all brain aneurysms are caused by AVMs, and their cause must be determined, as AVMs are more specific to HHT. Most individuals with a pulmonary AVM actually have HHT.

Telangiectases may sometimes be a sign of such other bleeding disorders as von Willebrand disease, which is a disorder of blood coagulation (clotting). Telangiectases may also naturally occur in pregnancy or chronic liver disease. Ataxia telangiectasia, another genetic condition involving telangiectases, should be considered if individuals have ataxia (problems with muscle coordination); movement and walking disorders are also often observed in patients with this condition.

Genetic testing is used to confirm a diagnosis of HHT. Tests are available for mutations in all of the known genes linked to HHT and will identify mutations in about 90% of patients who meet the Curaçao criteria for the disorder.

Treatment and management

Treatment for HHT is based on the specific symptoms an individual experiences. To assess the need for

KEY TERMS

Aneurysm—A localized blood-filled bulge or weak area in the wall of a blood vessel. The larger an aneurysm grows, the greater the risk of rupture. Aneurysms in the blood vessels of the brain are particularly dangerous.

Angiogenesis—The medical term for the formation of new blood vessels out of preexisting blood vessels.

Arteriovenous malformation (AVM)—Abnormal direct connection between the arteries and veins (blood vessels) that may range in size from very small to large. AVMs may lead to bleeding or aneurysm formation.

Cauterization—Process of burning tissue either with a laser or electric needle to stop bleeding or destroy damaged tissue.

Echocardiogram—A noninvasive technique that uses ultrasonic waves to examine the various structures and function of the heart.

Embolization therapy—Introduction of a coil or various substances into blood vessels in order to plug them and stop excessive bleeding.

Endoscope—A slender, tubular optical instrument used as a viewing system for examining an inner part of the body. With an attached instrument, the endoscope can be used for biopsy or surgery.

Epistaxis—The medical term for nosebleed.

Magnetic resonance imaging (MRI)—A diagnostic procedure that uses a combination of high-powered magnets, radio frequencies, and computers to generate detailed images of structures within the body.

Polyp—A mass of tissue bulging out from the normal surface of a mucous membrane.

Polyposis—The formation of numerous polyps in a body structure, most often the digestive tract or the nasal passages.

Stroke—A sudden neurological condition related to a block of blood flow in part of the brain, which can lead to a variety of problems, including paralysis, difficulty speaking, difficulty understanding others, or problems with balance.

Telangiectasis—Very small arteriovenous malformations that result in small red spots on the skin called “spider veins.”

treatment, a review of the patient’s medical history regarding nosebleeds and other bleeding episodes should be performed. About 35% of patients diagnosed with HHT have only mild symptoms and require no treatment.

There should be careful inspection of any telangiectases. Stool samples may be analyzed to determine whether there is any occult blood (blood that is not obvious to the naked eye); occult blood in the stool may indicate anemia. A complete blood count (CBC) can also determine whether anemia is a factor in the patient’s symptoms. Pulse oximetry involves studying a blood sample and determining whether the amount of oxygen absorption by red blood cells is normal. It can help to determine whether the lungs and heart are functioning properly, because their roles are to help oxygenate blood. Careful imaging of the heart by echocardiogram or chest x-rays can assess whether the heart structures are normal. Chest x-rays may identify pulmonary AVMs. Magnetic resonance imaging (MRI) of the head can visualize the brain to rule out any bleeding. Ultrasound of the liver and abdomen can help to rule out any AVMs in this area.

There are several options for those who experience chronic nosebleeds. Generally, sterile sponges and sprays may help absorb free-flowing blood. Another option is

laser therapy, used for individuals who have mild to moderate nosebleeds. A small laser beam is directed around each telangiectasis, causing clotting to occur and sealing the blood vessels. It is usually done under local anesthesia, and few complications exist. Nearly everyone sees improvements for several months, and the procedure may be repeated as needed. For more severe cases (sometimes requiring transfusions) there is septal dermoplasty, first pioneered in the 1960s. This procedure replaces the normally fragile lining of the nose with a tougher lining, using a skin graft from the thigh area. The procedure can be done with local or general anesthetic and has minimal complications. Some individuals never have nosebleeds again after the operation, but most of them experience a significant lessening of symptoms. Estrogen and aminocaproic acid (an amino acid) therapies have also been found to help with clotting in the nose. Estrogen improves the smoothness of layers of skin on the telangiectases, making them less fragile. Aminocaproic acid (Amicar) improves the clotting process by magnifying the protein responsible for clotting.

Gastrointestinal bleeding is one of the most difficult symptoms of HHT to treat. Endoscopy can help to identify the location of the AVM. Using an endoscopic probe, treatment can be attempted by laser or through

QUESTIONS TO ASK YOUR DOCTOR

- How do the various types of HHT differ from one another?
- How is HHT diagnosed?
- Would you recommend genetic testing for HHT?
- Please explain what telangiectasia is and how it affects my child's health.
- What is the prognosis for a child diagnosed with HHT, and on what factors is this prognosis based?

cauterization—sealing the injury with heat. These help to seal the telangiectasis or AVM. If bleeding is severe, iron therapy is often needed to help build more red blood cells and alleviate anemia. Hormone therapy (with estrogen and progesterone) has been helpful in many patients with chronic GI bleeding. No completely satisfactory treatment for liver AVMs has been established, but embolization therapy has been used. For more severe cases (usually in older individuals) liver transplantation may be considered.

Pulmonary AVMs are often treated with a procedure known as balloon embolization. A small tube is inserted into a large vein in the groin. It is passed through the blood vessels to the pulmonary AVM. A balloon or coil is placed into the artery leading into the AVM, blocking it completely, which stops the bleeding. The procedure usually takes one to two hours, with minimal recuperation time. Pulmonary AVMs can almost always be treated very well with this method. Women with HHT who become pregnant and have untreated pulmonary AVMs are at high risk of an internal lung bleed. They should be followed carefully throughout pregnancy and be treated during their second trimester to avoid this complication. Pregnant women with treated pulmonary AVMs appear to be at no higher risk for bleeding than pregnant women without pulmonary AVMs.

For generalized anemia, iron replacement and red blood cell transfusions may become necessary. People with HHT may develop medical problems unrelated to the condition, such as ulcers or colon cancer, which may cause additional GI blood loss.

Because telangiectases can occur in the mouth, dental work may be a particular problem for those with HHT. Bleeding in the mouth makes the area susceptible to oral bacteria, such as those on the gums. Bacteria can enter the bloodstream through the blood vessels in the

mouth and cause infections in other areas of the body. The best preventive measure is to take antibiotics before any dental work in order to prevent infection. Additionally, such medications as aspirin and NSAIDs (nonsteroidal anti-inflammatory drugs; examples include naproxen, ibuprofen, and ketoprofen) should be avoided because they can increase the risk of bleeding.

Experimental treatments for HHT include two anti-angiogenesis drugs: bevacizumab (Avastin), used to treat metastatic cancers, and thalidomide (Thalomid), used to treat multiple myeloma. As of 2015, neither drug had been approved by the Food and Drug Administration (FDA) specifically for the treatment of HHT.

Because effective treatment measures are available, unaffected at-risk individuals in a family should be screened for symptoms of HHT, especially for AVMs in the brain, lungs, and digestive tract.

Prognosis

Prognosis for individuals with HHT is good, assuming those with moderate or severe symptoms receive appropriate and timely treatments. Because many treatments are effective, proper screening is crucial to a good prognosis. Most patients will have a normal life expectancy.

Hereditary hypertrophic cardiomyopathy

Definition

Hereditary hypertrophic cardiomyopathy (HCM) is a genetic disorder characterized by abnormal thickening (hypertrophy) of the heart muscle (myocardium) in the absence of any other disease capable of causing such thickening. In HCM, the cardiomyocytes (the cells that make up the heart muscle) increase in size, resulting in the thickening of the muscle tissue. In addition, the cardiomyocytes are no longer in proper alignment, a condition known as myocardial disarray. Instead of being lined up in parallel rows, the cells form circular or disorganized patterns around small areas of connective tissue. Lastly, HCM disrupts the electrical functions of the heart.

HCM has been given many alternate names since the 1970s—by one account, as many as 75 different names. Some of the more common names that are still used include familial hypertrophic cardiomyopathy, asymmetric septal hypertrophy, hereditary ventricular hypertrophy, and rare familial disorder with hypertrophic cardiomyopathy. Increasingly, however, physicians are using the simple term “hypertrophic cardiomyopathy,” abbreviated HCM, because it is universally recognized that genetic mutations are the single most common cause of HCM. These mutations account for 50%–60% of diagnosed cases of HCM.

Description

HCM is characterized by functional impairment of the myocardium as a result of the thickening of the heart muscle. The most common location of this thickening is the intraventricular septum, which is the wall of tissue that divides the two lower chambers (ventricles) of the heart. However, any portion of the left ventricle may be affected. This condition is known as left ventricular hypertrophy, or LVH. As a result of the thickening of the muscle tissue, the left ventricle has less room to receive oxygenated blood, and the outflow of blood from the left ventricle through the aorta to the rest of the body is reduced.

Illustration of hypertrophic cardiomyopathy, showing enlargement of the muscular septum separating the left and right ventricles. (David Gifford/Science Source)

HCM can be divided into two types, obstructive and nonobstructive, depending on whether the outflow of blood through the aorta is obstructed by the movement of the mitral valve in the heart toward the intraventricular septum during the phase of the cardiac cycle known as systole (obstructive HCM), or whether the outflow of blood is simply less efficient (nonobstructive HCM). Obstructive HCM usually causes a heart murmur that a doctor can hear through a stethoscope during an office examination. The symptoms of both types of HCM are, however, similar, and both types are equally serious conditions.

Although most people with hereditary hypertrophic cardiomyopathy have no symptoms or report only mild occasional chest pains or shortness of breath, the condition can have major consequences. HCM can lead to life-threatening cardiac arrhythmias (abnormal heart rhythms). It is also the single most common cause of sudden cardiac death (SCD, which is unexpected death due to heart-related causes within an hour of symptom onset) among young athletes and a common cause of SCD in all age groups. In many people with HCM, sudden cardiac death is the first symptom of the disorder. Children as well as adolescents and adults with HCM can experience SCD, especially during exertion. It is most common, however, for the left ventricular hypertrophy associated

with HCM to become apparent in the patient's late teens or early twenties.

Genetic profile

HCM is inherited in an autosomal dominant pattern and is caused by mutations in any one of a number of genes that code for the proteins found in sarcomeres, which are the basic structures found in muscle cells. Sarcomeres are composed of alternating thick and thin protein filaments that alternately attach to and release from each other. This movement of the protein filaments relative to each other coordinates the contraction and relaxation of the heart muscle. Mutations in any of at least 22 different genes that code for various components of the sarcomere can lead to HCM, and over 1,500 mutations of these genes had been identified as of 2015. About 50%–60% of patients with clinical symptoms indicating HCM will have a mutation in at least one of nine sarcomere genes. The most common genes with mutations affecting the sarcomeres in cardiac muscle are as follows:

- **MYH7.** About 40% of mutations associated with HCM involve this gene, which codes for myosin, the major protein constituting the thick filament in cardiac sarcomeres. It is not clear, however, how mutations in the *MYH7* gene lead to the symptoms of HCM. The gene is located on the long arm of chromosome 14 at 14q12.
- **MYBPC3.** Another 40% of mutations found in patients with HCM involve this gene, located on the short arm of chromosome 11 at 11p11.2. It codes for a protein that provides structural support for the thick filaments in sarcomeres.
- **TNNT2.** About 5% of HCM mutations are associated with this gene, which codes for troponin, a protein found on the thin filaments in sarcomeres. This gene is located on the long arm of chromosome 1 at 1q32.
- **TPM1.** About 2% of cases of HCM are associated with mutations in this gene. It is located on the long arm of chromosome 15 at 15q22.1.
- **PRKAG2.** This gene codes for an enzyme that monitors the energy levels in cells. It is located on the long arm of chromosome 7 at 7q36.
- **TNNI3.** This gene codes for a protein found only in heart muscle that coordinates the contraction of the heart. It is located on the long arm of chromosome 19 at 19q13.4. Mutations in this gene account for about 57% of cases of HCM.
- **MYL3.** Mutations in this gene account for about 1% of known cases of HCM. It is located on the short arm of chromosome 3 at 3p21.31.
- **TTN.** This gene codes for a muscle protein known as titin or connectin. It is located on the long arm of chromosome 2 at 2q24.3.

- **MYL2.** The *MYL2* gene codes for a type of myosin that is found in the ventricular muscle of the heart. It is located on the long arm of chromosome 12 at 12q23-q24.
- **ACTC1.** This gene codes for a form of actin (the protein found in the thin filament of sarcomeres) that is found only in cardiac muscle. The gene is located on the long arm of chromosome 15 at 15q14.
- **CSRP3.** This gene codes for a protein that plays an important role in the production and differentiation of muscle cells. It is located on the short arm of chromosome 11 at 11p15.1.

Other genes with mutations that have been linked to HCM include the *MYH6* gene on chromosome 14 at 14q12, the *VCL* gene on chromosome 10 at 10q22, the *MYOZ2* gene on chromosome 4 at 4q26, the *JPH2* gene on chromosome 20 at 20q12, the *PLN* gene on chromosome 6 at 6q22.1, the *CALR3* gene on chromosome 19 at 19p13, the *NEXN* gene on chromosome 1 at 1p31.1, the *MYPN* gene on chromosome 10 at 10q21, the *ACTN2* gene on chromosome 1 at 1q43, the *LDB3* gene on chromosome 10 at 10q23, and the *TCAP* gene on chromosome 17 at 17q12. Given the high number of genes already known to be associated with HCM, it is highly likely that additional genes linked to the condition will be identified in the future.

Not all cases of HCM result from genetic mutations. Other causes include disorders that increase pressure within the heart, such as untreated hypertension or aortic stenosis (narrowing of the aorta). Other systemic diseases that may cause HCM include amyloidosis (accumulation of abnormally folded proteins called amyloids in the heart) and Fabry disease (a disorder in which fatty substances called glycolipids build up in the blood vessels and tissues of the heart).

Demographics

HCM is the single most common genetic disease of the heart in the United States, affecting about 1 in every 500 people or between 0.05% and 0.2% of the population. There were about 600,000 people in the United States with HCM as of 2015. Most cardiologists believe that the rate is similar worldwide. HCM is found in all races and ethnic groups and affects males and females equally.

Among athletes with HCM, African American athletes appear to be at greater risk of SCD than Caucasian or Asian athletes, but the reason for this difference is unclear.

Signs and symptoms

It is possible for a person with HCM to have no symptoms at all or to have sudden cardiac death as the

initial symptom. In families with a history of HCM, different members may vary considerably in the severity of the symptoms they report. Patients who do have symptoms usually report one or more of the following. It should be noted, however, that none of these is unique to HCM.

- **Dyspnea** (feeling short of breath or having difficulty breathing): This is the single most common symptom of HCM.
- **Syncope and presyncope**: Syncope refers to fainting and loss of muscle strength due to a decrease of blood flow to the brain, usually as a result of low blood pressure. Presyncope is a milder form of the condition in which the person does not completely lose consciousness or muscle strength but feels lightheaded and weak.
- **Angina**: Angina is a sensation of pain, squeezing, or pressure in the chest caused by a restriction in the blood supply to the cardiac muscle. Angina associated with HCM is typically increased by exertion.
- **Dizziness**.
- **Palpitations**: Palpitations are feelings or sensations that the heart is racing, beating irregularly, or pounding. They may be felt in the neck or throat as well as the chest.
- **Congestive heart failure (CHF)**: This condition is uncommon in HCM but is sometimes seen when the patient's left ventricle becomes stiff as well as abnormally thick. Stiffening of the ventricle lowers its ability to fill with enough blood to meet the body's needs, as well as reduces its ability to pump effectively.
- **Orthopnea**: Orthopnea refers to shortness of breath that occurs when a person is lying flat; for example, in bed trying to fall asleep.

The following factors increase a patient's risk of SCD: family history of SCD, recurrent episodes of syncope, prior history of cardiac arrest or ventricular fibrillation, thickness of the left ventricle equal to or greater than 30 mm (about 1.18 in.), and abnormal blood pressure readings during exercise.

Diagnosis

Clinical diagnosis

The diagnosis of HCM is based on a combination of a detailed family history as well as a history of the patient's symptoms, followed by an office examination and more detailed tests of heart function. When the doctor listens to the patient's heart through a stethoscope, he or she may hear various abnormal heart sounds, including a heart murmur, a double apical impulse, a split-second heart sound, and a so-called fourth heart sound.

No specific blood or urine tests are used to diagnose HCM. The diagnostic tests used most often are electrocardiography; echocardiography, in which two- or three-dimensional or Doppler ultrasound is used to create images of the heart; cardiac catheterization, in which a catheter is inserted into the left ventricle to determine the degree of outflow obstruction; and cardiac MRI, which is particularly useful when echocardiography does not give clear results. Cardiac MRI can also be used to evaluate the effectiveness of surgical treatments for HCM.

Genetic testing

Genetic testing for HCM is a complex process because of the sheer number of genes known to be associated with HCM. It is not ordinarily used simply to confirm a clinical diagnosis of HCM. It is also not used to screen large populations, such as student or professional athletes, because its use as a screening tool is not cost-effective.

In families with a history of SCD and other heart disorders that suggest HCM, genetic testing is considered a test of the family as a whole rather than of a specific individual. Such testing begins with the family member who best meets the diagnostic criteria for HCM. That person is then tested using a multigene panel. If a disease-causing mutation is identified, the next step is to test at-risk family members (usually first-degree relatives) for the family-specific mutation. Those who do not have the mutation do not need routine cardiac evaluation. Those who do have the mutation are asked to have cardiac evaluations at regular intervals. Family members are also usually asked to meet with the cardiologist and a genetics counselor to discuss the findings of the test and treatment recommendations.

Genetic testing for HCM also has limitations. About 30% of mutations causing HCM are *de novo*, which means that the mutation will not appear in other family members. In addition, not all persons diagnosed with HCM will have a mutation that can be identified with current testing strategies. Lastly, the identification of a disease-causing mutation cannot be used by itself to predict the age of onset of symptoms in a given individual or the outcome of treatment.

Treatment and management

There is no cure for HCM. Treatment and management of the disease is based on a combination of lifestyle modification, medications, and surgical interventions. The basic goals of treatment are to increase the volume of the left ventricle, increase the compliance (flexibility) of the ventricle, and increase the dimensions of the ventricle's

KEY TERMS

Actin—A protein that interacts with myosin during the process of muscle contraction.

Angina—A sensation of chest pain, squeezing, or pressure, usually arising from reduced blood supply to the heart muscle due to obstruction or spasm of the coronary arteries.

Atria (singular, atrium)—The two upper chambers of the heart.

Cardiac arrest—A sudden stop in the circulation of the blood due to the failure of the heart to contract effectively or at all. It is potentially reversible but if untreated can lead to sudden cardiac death.

Cardiomyocytes—The muscle cells that make up heart muscle tissue.

Cardiomyopathy—A thickening of the heart muscle.

De novo mutation—A genetic mutation that is seen for the first time in the affected person, not inherited from the parents.

Dyspnea—Shortness of breath or difficulty in breathing.

Hypertrophy—Increase in the size of a tissue or organ brought on by the enlargement of its cells rather than cell multiplication.

Mitral valve—The heart valve that lies between the left ventricle of the heart and the left atrium. It is also called the bicuspid valve because it has two leaves or flaps.

Myocardial disarray—A condition in which the cells in the heart muscle are aligned in a disorderly fashion rather than in parallel lines.

Myocardium—The medical term for the muscle of the heart.

Myosin—The most common protein in muscle cells, which interacts with actin during muscle contraction to form actomyosin.

Palpitations—Perceived rapid or abnormal heartbeats associated with awareness of the heart's contractions in the chest. Palpitations may be caused by anxiety, caffeine, some drugs of abuse, or certain prescription medications, as well as by structural abnormalities of the heart.

Sarcomeres—The basic functional units of striated muscle tissue. Sarcomeres consist of fibrous proteins that slide past each other as the muscle contracts and relaxes.

Septum—In anatomy, a wall of tissue that divides a body cavity or structure into smaller sections. The intraventricular septum is the tissue that divides the two lower chambers of the heart.

Sudden cardiac death (SCD)—A term used to describe an unexpected death due to cardiac causes that occurs within an hour of symptom onset in a person with known or unknown heart disease.

Syncope—A brief loss of consciousness caused by insufficient blood flow to the brain.

Systole—The rhythmic contraction of the heart, particularly of the ventricles, in which blood is pumped through the aorta and the pulmonary artery.

Ventricles—The two lower chambers of the heart. The right ventricle pumps blood to the lungs, and the left ventricle pumps oxygenated blood through the aorta into the general circulation.

outflow tract. The medications and surgical interventions used to treat adults are also used in children with HCM.

Lifestyle modification

Adults diagnosed with HCM must abstain completely from high-energy competitive athletic activity and such highly strenuous activities as shoveling snow or lifting very heavy objects. These precautions are necessary to lower the risk of sudden cardiac death. Other lifestyle modifications include maintaining a healthy weight and using alcohol only in moderation, as heavy drinking can trigger heart arrhythmias.

Children diagnosed with HCM require careful monitoring of their activities, particularly as they approach puberty. They should be given an annual echocardiogram

as they progress through puberty. They should also be advised to avoid competitive sports and strenuous activity.

Medications

The types of medications most often prescribed for patients with HCM are beta blockers, calcium channel blockers, and antiarrhythmic agents. Beta blockers, which include such drugs as propranolol, nadolol, sotalol, atenolol, and metoprolol, are given to slow the heart rate and reduce the heart's force of contraction. These drugs relieve palpitations, chest pain, and dyspnea.

Calcium channel blockers, which are also called calcium antagonists, improve the filling of the heart, lower blood pressure, and slow the heart rate. Verapamil is the drug in this class most often used to treat HCM.

QUESTIONS TO ASK YOUR DOCTOR

- How can you tell the difference between hereditary hypertrophic cardiomyopathy and other heart disorders that produce the same symptoms?
- Which diagnostic tests will you order to determine whether I have HCM or some other heart disorder?
- If I do have HCM, will you recommend genetic testing for me or for another family member?
- Do you think my HCM can be managed with medications, or will I need to have surgery?
- Will I have a normal life expectancy?

Antiarrhythmic drugs given to treat HCM include amiodarone, which is a very powerful medication with potentially severe side effects. It requires strict monitoring by the patient's physician. The other drug in this group is disopyramide, which can be used to help relieve obstruction in the obstructive form of HCM.

Some patients with HCM benefit from the use of diuretics to reduce fluid overload, although diuretics must be used with caution in patients with obstructive HCM. Some patients with a risk of blood clots in the atria (the upper chambers of the heart) are prescribed anticoagulants (blood thinners). Warfarin is the anticoagulant most often given to patients with HCM.

Surgery

Surgical interventions in the management of HCM are usually done when the patient's symptoms cannot be controlled by medications alone. Surgical treatment may include the following:

- **Septal myectomy.** This procedure involves open heart surgery to remove a portion of the intraventricular septum in order to decrease obstruction of the ventricle's outflow tract. It has been performed since the 1990s and has an 85% success rate. The risks of septal myectomy include bleeding, infection, perforation of the septum, stroke, and possible death.
- **Alcohol septal ablation** (also called catheter septal ablation). This is a technique invented by German surgeon Ulrich Sigwart in 1994. It involves the injection of 96% alcohol through a catheter into one or more branches of the left anterior descending artery. The alcohol causes infarction (tissue death) of some of the tissue in the intraventricular septum, thus reducing the

abnormal thickness of the septum. Alcohol septal ablation is in effect a controlled heart attack. It produces results similar to a septal myectomy but is less invasive because it does not involve opening the chest wall. It appears to be beneficial in older patients for whom a septal myectomy would be relatively risky. It is the procedure of choice for HCM in a growing number of medical centers.

- **Implantation of an ICD.** An implantable cardioverter defibrillator, or ICD, is a device that can be implanted in the patient's chest to lower the risk of sudden cardiac death. The device automatically recognizes and treats arrhythmias. It appears to be most useful in patients at high risk of SCD.
- **Heart transplantation.** Heart transplantation is the treatment of last resort for patients with HCM who do not benefit from medications or other surgical interventions. It is also the only option for patients in end-stage heart failure. The procedure has a high rate of success, with 94% of patients still alive seven years after transplantation.

Prognosis

The mortality rate for adults diagnosed with HCM has been variously reported as low as 1% per year to a higher rate of 3%–6% per year. In general, mortality rates in adults with HCM have improved since the 1970s, partly as a result of better diagnostic techniques and a higher index of suspicion, and partly as a result of more effective treatments. Most adults with HCM, particularly those with milder symptoms, will have a normal life expectancy with appropriate treatment and monitoring.

The prognosis for children diagnosed with HCM is better than was previously thought, largely as a result of improved recognition of the condition in its earliest stages. The mortality rate among children with HCM is about 1% per year, although a small subset has been reported as having a mortality rate of 4%–5% per year. Among adolescent athletes who die of SCD, the median age is 17 years, with basketball and football being the most common sports associated with SCD. Children who are not in this high-risk subgroup may have a normal life expectancy.

Hereditary multiple osteochondromas

Definition

Hereditary multiple osteochondromas (HMO), previously known as hereditary multiple exostosis (HME), refers to a group of disorders characterized by abnormal bone growth. The major symptom is the development of osteochondromas. Osteochondromas are classified as benign growths of bone tumors covered with cartilage that begin in the metaphysis of long bones and grow outward into the surrounding tissue. Osteochondromas typically produce pain and other complications by pressing on nearby tissue, they may limit movement of joints, and in some cases they must be surgically removed.

Description

An osteochondroma is a benign (noncancerous) bony growth. This does not refer to a normally shaped bone that has simply grown larger than normal. Rather, an osteochondroma is a bump, or nodule, of excess bone on a long bone, usually with overlying cartilage. That is why HMO is sometimes referred to as the "bumpy bones" disease. Other names for the disorder include multiple hereditary exostosis (MHE), multiple cartilaginous exostosis, osteochondromatosis, and diaphyseal aclasis.

People with HMO typically develop anywhere from several to many osteochondromas during their life, mostly during childhood and adolescence due to the growth of bone that occurs at this stage of life. Osteochondromas vary in size and can develop on most long bones in the body. An osteochondroma may present no signs or symptoms, or it may cause pain and other complications by pressing on nearby soft tissue (nerves, blood vessels, tendons, internal organs) or on another bone at a joint. Osteochondromas that do cause problems are often surgically removed. HMO can cause differences in the shape of bones or reduce their growth rate. Thus, people with HMO tend to be somewhat shorter than average and may have limited movement in certain joints. People with HMO are not at risk for tumor development in other tissues.

HMO is an autosomal dominant condition, and most people with the disorder have family members who are affected. A small percentage of people who carry an *HMO* gene do not develop any recognizable osteochondromas. The vast majority of osteochondromas are benign growths, but a small percentage can become malignant (cancerous chondrosarcoma).

Genetic profile

Three different types of HMO are known to exist: HMO type I, HMO type II, and HMO type III. There appear to be no obvious differences in the presentation and course of the disorder among the three types. Instead, the designations correspond to the three genes—*EXT1*, *EXT2*, and *EXT3*, respectively—that have been linked to HMO. The protein produced by the *EXT1* gene on chromosome number 8 is called exostosin-1, and the *EXT2* gene on chromosome number 11 produces exostosin-2. The *EXT3* gene is located on chromosome number 19.

HMO is an autosomal dominant condition, which means that any person who carries an *HMO* gene has a 50% chance of passing it on each time he or she has a child. Ninety percent of people with HMO have a positive family history. In the other 10% of cases, HMO occurred in that person for the first time as the result of a new mutation in one of the *EXT* genes. Regardless of whether someone inherits HMO from a parent or it occurs

KEY TERMS

Chondrosarcoma—A malignant tumor derived from cartilage cells.

Diaphysis—The middle portion, or shaft, of a long bone.

Epiphysis—The end of long bones, usually terminating in a joint.

Exostosis—An abnormal growth (benign tumor) on a bone.

Metaphysis—An area of softer bone and cartilage in long bones between the diaphysis (shaft) and epiphysis (end).

Osteochondromatosis—Another name for hereditary multiple exostoses, meaning a growth of bone and cartilage.

in him or her for the first time, each of that person's children is still at a 50% risk.

A tumor is the result of cells that undergo uncontrolled replication/division. People often equate the word “tumor” with cancer. However, a tumor is simply a growth, and it may be malignant (cancerous) or benign (noncancerous). Technically, osteochondromas are tumors, but they are nearly always benign.

EXT1 and *EXT2* belong to a class of genes known as *tumor suppressors*. In normal circumstances, tumor suppressor genes prevent cells from either replicating at all or replicating too quickly. If both copies of a tumor suppressor gene are mutated (inactivated), control of cell replication/division is lost. A person who inherits HMO type I or HMO type II already has one *EXT1* or *EXT2* gene inactivated from the moment he or she is conceived. However, abnormal bone growth does not occur unless the other gene of the pair also becomes inactivated. This second gene mutation, called loss of heterozygosity (LOH), appears to be an unlikely, random event, which explains why there is not abnormal growth throughout all of the bones. Only the occasional bone cell that undergoes LOH has a chance of becoming an osteochondroma. Any person without HMO can develop a single osteochondroma, and 2% of all people do. However, osteochondroma development is much less likely when two random mutations of an *EXT* gene in a bone cell must occur, rather than just one.

Demographics

The prevalence of HMO is estimated at about one in 75,000. There does not appear to be any significant

difference in prevalence between the major ethnic groups. Most studies have found that males with an *HMO* gene tend to have more obvious and severe symptoms than females. The reason for this is unknown. This makes it appear as though males are more likely to inherit HMO, when in fact they are just more likely to be diagnosed.

Most people with HMO have either HMO type I or HMO type II. Only a small percentage of HMO cases are linked to the *EXT3* gene. Further study of the *HMO* genes should establish an accurate prevalence for each type.

Signs and symptoms

About half of all people with HMO are diagnosed by the time they are three years old. Only 5% of newborns that carry an *HMO* gene show some signs at birth, but 95% of all people with the condition show noticeable signs by the time they are 12 years of age.

Osteochondromas primarily develop during the period of rapid bone growth from infancy through late adolescence. A small percentage of newborns already have noticeable osteochondromas at birth, and rare individuals with HMO may develop osteochondromas as adults. The number of osteochondromas varies from person to person, even within families. The average affected person develops six osteochondromas during his or her life.

Both the locations and sizes of osteochondromas vary. The most commonly affected bones are those of the arms (humerus, radius, and ulna), legs (femur, tibia, and fibula), hands (carpals and metacarpals), and feet (tarsals and metatarsals). Osteochondromas on the arm or leg nearly always develop near the joints (elbow, wrist, knee, or ankle) due to the fact that osteochondromas develop from the metaphysis, rather than in the middle of the long bones. About 70% of people with HMO have an osteochondroma or bone deformity around the knee. Flat bones, such as the scapula (shoulder blade) and pelvis, may be affected. The ribs and bones of the shoulder girdle occasionally develop growths, but osteochondromas are hardly ever seen on the spine or bones of the skull. Some osteochondromas under the skin may be barely noticeable to the touch (less than 1 cm in height), while others produce a noticeable bump (1–2 cm in height). Growths on the flat bones may be somewhat larger.

The most common problem in HMO is osteochondromas that cause compression and irritation of adjacent soft tissue, such as skin, nerves, and blood vessels. These types of growths can cause chronic pain until they are removed, and accidentally hitting them against something solid can be especially painful. Osteochondromas that

QUESTIONS TO ASK YOUR DOCTOR

- Am I/is my child a surgical candidate?
- How can I/my child prevent the osteochondroma from turning into a chondrosarcoma or worse?
- How often should I/my child be monitored for new growths?
- Will I/my child be able to play sports?

grow near the ends of long bones may interfere with normal movement of a joint. Many children with HMO have difficulties with their knees, both in range-of-motion and with angular deformities (“knock-kneed”). An uncommon, but more complicated problem is a large osteochondroma on the inside of the pelvis that results in compression of the intestine or urinary tract.

HMO affects the growth centers of bones (metaphyses and epiphyses), which can result in abnormal modeling (structure) of the affected bones. Reduction in size and bowing of bones are the most frequent structural anomalies seen. Consequently, people with HMO tend to be somewhat shorter than average—final height in men averages 170 cm (66 in.), while the average height in women is 160 cm (62 in.). Differential rates of growth between a child’s legs or arms can result in leg- or arm-length discrepancy, sometimes reaching 2 cm (1 in.) or more. Leg-length discrepancy can result in hip pain and problems with walking caused by tilting of the pelvis.

The most serious complication in HMO is the progression of a benign osteochondroma to a malignant (cancerous) state, known as a chondrosarcoma. This happens in slightly less than 1% of all people with the condition. Chondrosarcomas can develop in children, but those few cases that do occur are usually in adults. An undetected bone malignancy always presents a risk for metastasis—the spreading of cancerous cells elsewhere in the body—which is one of the most dangerous complications of any cancer. Most chondrosarcomas should be detected and treated early because they are usually associated with rapid growth of an osteochondroma accompanied by pain.

Diagnosis

The diagnosis of HMO is usually made when noticeable osteochondromas first appear. Any person who is at risk for the condition because of a family history is more likely to be accurately diagnosed at a younger age. The occurrence of a single osteochondroma in an otherwise

healthy person is not rare. Therefore, two or more osteochondromas must be present in order to make the diagnosis of HMO (although a single osteochondroma detected in someone who is known to be at 50% risk for HMO is highly suggestive of the diagnosis).

Osteochondromas are not always detectable by physical examination. Consequently, an x-ray study of the commonly affected bones (skeletal survey) in questionable cases is the best method of confirming or excluding the diagnosis. This is especially true in cases in which a child is known to be at risk for HMO (positive family history).

Unlike some genetic disorders with which many people with the condition have the same gene mutation, most individuals/families with HMO tested so far have had different mutations in either *EXT1* or *EXT2*. Therefore, while predictive or confirmatory genetic testing might be possible within a family (assuming the gene mutation is detectable), direct testing of *EXT1/EXT2* in a person with a negative or uncertain family history is not yet reliable enough to use as a diagnostic tool.

Treatment and management

The only treatment for osteochondromas that present problems is to remove them surgically. In those instances in which the osteochondroma is easily accessible, surgical removal is straightforward and carries very little risk. On the other hand, an osteochondroma that involves one of the joints or is less accessible—somewhere on the inner surface of the pelvis, for instance—may require involved surgery. A few people with HMO will never require surgical intervention, but most have at least one surgery, and some will have many. A child who is noted to have uneven or accelerated growth of a long bone in the arm or leg may be offered a procedure to straighten the bone or reduce its growth rate.

No external factors are known to cause or prevent the growth of osteochondromas. Those persons diagnosed with HMO, as well as children at risk, must be taught to monitor themselves for unusual changes in bone growth.

Anyone with HMO should have lifelong, periodic examinations by an orthopedic surgeon to look for and address any problematic osteochondromas and to screen for chondrosarcoma. Since osteochondromas and other bone-growth problems occur primarily in childhood, special attention, care, and education about their disorder is often needed for children with HMO.

Prognosis

The majority of people with HMO lead active lives, and their lifespan is not reduced. Surgery to remove

problematic osteochondromas will likely remain the primary method of treatment for some time. The hope is that further analysis of the *EXT* genes and their protein products will lead at some point to a more targeted approach to reducing or eliminating abnormal bone growths altogether.

Hereditary neuropathy with liability to pressure palsies

Definition

Hereditary neuropathy with liability to pressure palsies (HNPP) is a rare disease that can range in severity from benign to serious. It is characterized by swelling of the myelin sheath that leads to irritation of the nerves, particularly in the arms and legs. Many people who have the condition are unaware that they have it. For a small percentage of affected people, HNPP may be painful and debilitating.

Other names for HNPP include:

- tomaculous neuropathy
- compression neuropathy
- entrapment neuropathy
- familial pressure-sensitive neuropathy
- hereditary motor and sensory neuropathy
- inherited tendency to pressure palsies

Description

HNPP is characterized by episodes of numbness, tingling, and weakness in extremities. The physical sensations may be accompanied by physiologic symptoms such as foot drop, difficulty walking, and difficulty with fine motor skills such as writing. These episodes may vary in length and duration, occurring rarely or regularly and lasting anywhere from a few minutes to several weeks or months.

These episodes are called "pressure palsy" and are caused by nerve injury from routine activities, stretching, or repetitive motions. In individuals with HNPP, activities that would not injure others cause nerves to demyelinate, or to lose the protective covering. When this occurs, it leaves the nerves exposed and leads to the symptoms of HNPP. Eventually, the nerves may heal or remyelinate as the covering grows back, and the symptoms may subside.

In most individuals with HNPP, symptoms usually begin after adolescence. Episodes generally occur for a short period of time. Some people with HNPP have no symptoms, leading researchers to suspect that the condition may be more common than previously thought. Others may have an extreme form in which episodes are near continuous. In this event, the condition may become a permanent disability.

Genetic profile

HNPP is caused by mutations in the *PMP22* gene. Researchers are not certain of the exact function of this gene, but they suspect the *PMP22* gene is involved in production of myelin, the substance that provides a protective covering for nerves. It is likely that mutations in the *PMP22* gene affect myelin production, causing it to become unstable and leading to the symptoms of HNPP.

HNPP is inherited in an autosomal dominant pattern, which means an individual only needs to have one mutated copy of the gene for the condition to develop.

Demographics

HNPP is an extremely rare condition, affecting between 2 and 5 per 100,000 individuals. The estimated age range for observed symptoms is from 8 to 72 years.

KEY TERMS

Myelination—Production and maintenance of the myelin sheath.

Neuropathy—A general term for disorders of the nerves of the peripheral nervous system.

Neurotransmitters—Chemicals that relay signals between a neuron and another cell.

Paralysis—Complete loss of muscle function for one or more muscle groups, often with loss of feeling and mobility in the affected area.

Most occurrences of observed symptoms take place during the affected person's 20s and 30s.

Signs and symptoms

HNPP is characterized by numbness, tingling, and weakness of the extremities. The numbness may vary, occurring as a mild discomfort to some, while others experience significant numbness even describing it feeling as if “an arm has been deadened with Novocain.” Similarly, muscle weakness may be a mild irritant or a debilitating condition, varying from hand weakness to the inability to hold a pen and write, walk, or use the arm or leg.

The duration of symptoms may be highly variable as well. Some individuals experience only momentary discomfort, other have symptoms for periods of hours or days, and others still may have almost continuous symptoms that are so limiting the condition becomes a disability.

The cause of HNPP is a mutation that eliminates an important protein on gene *PMP22* on chromosome 17. The effect of this mutation is the swelling of the myelin sheath of the nerve cells in the peripheral nervous system. The myelin sheath serves as insulation for the axon, which is the cable of the nerve cell through which neurotransmitters run with messages from the brain to the muscular-skeletal system and from the muscular-skeletal system to the brain. Without the tight insulation of the myelin sheath, the neurotransmitters running through the axon are not contained, which interferes with effective neural communication.

How this neurological problem is manifested depends on the metabolism of the person affected and the severity of the event generating the emergence. When the symptoms are recurrent, they are not usually manifested in the same nerves as in previous episodes. The usual symptoms are numbness, pain, weakness, or paralysis. Some of those affected experience carpal tunnel

syndrome. Genetic researchers are particularly interested in HNPP because of its relationship with another, more common disorder. Charcot-Marie-Tooth disease (CMT) is caused by a duplication of the *PMP22* gene, whereas HNPP is caused by a deletion or mutation of that gene. The two disorders sometimes share symptoms and are often mistaken for each other.

Diagnosis

The diagnosis of HNPP begins with observing a patient who has recurring episodes characterized by numbness, pain, weakness, paralysis, or a combination of these. The diagnosis would also be dependent on a search of the family history for evidence that the condition may have been inherited.

The only sure diagnosis is a genetic screening that detects mutations in the *PMP22* gene.

Treatment and management

The main goal of treatment is to relieve the irritation of the nerve damage. Adaptive equipment such as wrist splints, protective pads for elbows and knees, and ankle-foot orthoses (braces) can relieve episodes. Prevention of the nerve pressure is the best treatment for those who have been diagnosed. Pacing is an important habit to develop, as it relieves pressure. Avoiding repetitive movements as well as staying in one position for any prolonged period is recommended.

Under extreme conditions, surgery to remove the compression on the nerve may be recommended. Many individuals with HNPP experience spontaneous remission, and their condition wanes without treatment. In such cases, surgery is unnecessary. Furthermore, surgery does not always bring results, and when it does, the results do not always last.

Many people with HNPP avoid any episode by maintaining good physical fitness. Once diagnosed, individuals with HNPP must avoid activities and conditions that could put undue pressure on the nerves. Activities that could become repetitive can be interchanged with other activities to reduce repetitive motion. People can avoid remaining in one position too long by getting up, stretching, or pacing.

Prognosis

There is no cure for HNPP. However, with conscientious maintenance, most affected people do not have any prolonged periods of troublesome episodes. Nerves destroyed in an episode eventually repair themselves. However, with increased episodes, the nerves take longer to repair.

QUESTIONS TO ASK YOUR DOCTOR

- What are the chances that I will have continuous episodes of HNPP?
- What adaptive equipment is best for me?
- How often do people with my condition become disabled?
- Would surgery help my condition?
- How do other people with my level of HNPP adapt their lifestyles?
- Should my relatives have testing for HNPP?

Hereditary pancreatitis

Definition

Hereditary pancreatitis is a rare genetic condition beginning in childhood that is characterized by recurrent episodes of inflammation of the pancreas, causing intense abdominal pain, nausea, and vomiting. Most episodes

resolve on their own, but serious complications can arise, ranging from diabetes and poor digestion to bleeding, infection, pancreatic cancer, and death. Medical treatment can help alleviate some of the symptoms, and occasionally surgery may be needed to treat some of the complications.

Description

The pancreas is an organ located in the abdomen that has several functions. First, the pancreas aids in the digestion of food through the production of digestive enzymes. Digestive enzymes are proteins that break down food components, including sugars, fats, and other proteins, so that they can be absorbed and used by the body. Normally, the digestive enzymes are stored within the pancreas in an inactive form. In response to food intake, the enzymes are released from the pancreas and travel through the pancreatic duct into the small intestine, where they become activated and begin to digest food.

The second function of the pancreas is to maintain proper sugar balance in the blood. The pancreas produces several hormones, including insulin and glucagon, that are secreted into the bloodstream and act to increase or decrease sugar levels within the blood.

Pancreatitis is a condition in which the pancreas becomes irritated and inflamed. In most cases, the condition is caused by excessive alcohol use or by the presence of gallstones, but it can also be caused by medications, viral infections, injury to the abdomen, abnormal structures of the pancreas, and several metabolic disorders. In some rare instances, pancreatitis is caused by a genetic abnormality that is passed down from parent to child and is called hereditary pancreatitis.

In hereditary pancreatitis, an individual inherits a genetic abnormality in one of the digestive enzymes produced by the pancreas, called trypsin. Normally, trypsin is stored within the pancreas in an inactive state and only becomes activated when it travels to the small intestine and encounters food to digest. However, in individuals with hereditary pancreatitis, the trypsin becomes activated while still in the pancreas and begins to digest the pancreas itself, causing irritation and inflammation. Damage to the blood vessels in the pancreas can result in bleeding or fluid leaks from the blood vessel into the abdominal cavity. The digestive enzymes also gain access to the bloodstream through the damaged blood vessels and begin circulating throughout the body, causing further damage.

It is unclear what causes the abnormal trypsin enzyme to become activated and begin digesting the pancreas, but some studies have shown that emotional stress, alcohol, or fatty foods may trigger the process. After

Hereditary Pancreatitis: pedigree analysis chart. (Gale)

time, recurrent episodes of pancreatitis may leave the pancreas permanently irritated and damaged, a condition called chronic pancreatitis.

Genetic profile

Hereditary pancreatitis is a genetic disease and can be inherited or passed on in a family. The genetic abnormality for the disorder is inherited as an autosomal dominant trait, meaning that only one abnormal gene is needed to inherit the disease and that a parent with the disease has a 50% chance of transmitting the abnormal gene and disease to a child.

Changes in the gene for the digestive enzyme trypsin (located on human chromosome 7, at 7q35) are responsible for the disease, and more than five different genetic changes in the trypsin gene have been identified. Changes in other genes may also cause hereditary pancreatitis, as recent studies have discovered families with this condition with mutations in other genes, possibly on chromosome 12.

Demographics

The annual incidence of all forms of pancreatitis is about 1 per 10,000 people. However, hereditary pancreatitis is a rare cause of all pancreatitis and makes up only about 2% of the total cases. While the true prevalence of the condition is difficult to measure, it is estimated that

at least 1,000 individuals in the United States are affected by hereditary pancreatitis.

Approximately 100 different families with hereditary pancreatitis have been identified since the condition was first recognized in 1952. The largest concentration of hereditary pancreatitis in the United States is in the central Appalachian region, which extends from southern Ohio to eastern Kentucky and Tennessee, western Virginia and North Carolina, and northern Georgia.

Signs and symptoms

Hereditary pancreatitis begins with recurrent episodes of pancreatitis during childhood. The age of the first episode of pancreatitis may range from infancy to over 30 years old, but 80% of patients will show the first episode of pancreatitis before 20 years old, and the average individual shows a first episode at approximately 10 to 12 years old.

People who are experiencing an episode of pancreatitis have severe abdominal pain, nausea, and vomiting that is greatly worsened by eating. The pain is often described as steady and dull pain that is centered on the navel and may extend to the back. As a result of fluids that leak from the pancreas and surrounding vessels into the abdomen, the abdomen may swell.

The severity and duration of each episode may range from only occasional abdominal discomfort to prolonged,

KEY TERMS

Abscess—A localized collection of pus or infection that is walled off from the rest of the body.

Amylase—A digestive enzyme found in saliva or pancreatic fluid that breaks down starch and sugars.

Autosomal dominant—A pattern of inheritance in which only one copy of a defective gene on a non-sex chromosome is required for a disease or inherited trait to develop in an individual.

Computed tomography (CT) scan—An imaging procedure that produces a three-dimensional picture of organs or structures inside the body, such as the brain.

Diabetes—An inability to control the levels of sugar in the blood due to an abnormality in the production of, or response to, the hormone insulin.

Digestive enzyme—Proteins secreted by the pancreas that enter the small intestine and break down food so it can be absorbed by the body.

Gastroenterologist—A physician who specializes in disorders of the digestive system.

Hormone—A chemical messenger produced by the body that regulates specific bodily functions such as growth, development, and reproduction.

Insulin—A hormone produced by the pancreas that is secreted into the bloodstream and regulates blood sugar levels.

Intravenous—A route for administration of fluids, nutrients, blood products, or medications. A small flexible plastic tube is inserted into a vein by way of a needle to establish this route.

Lipase—A digestive enzyme found in pancreatic fluid that breaks down fats.

Nasogastric tube—A long flexible tube inserted through the nasal passageways, down the throat, and into the stomach. Used to drain the contents of the stomach.

Pancreas—An organ located in the abdomen that secretes pancreatic juices for digestion and hormones for maintaining blood sugar levels.

Pseudocyst—A fluid-filled space that may arise in the setting of pancreatitis.

Ranson criteria—A system of measurements, including age and blood testing, that can be used to predict the outcome of a person who has been hospitalized for an episode of pancreatitis.

Shock—An inability to provide the body with the oxygen it requires, sometimes due to large amounts of bleeding or fluid loss.

Trypsin—A digestive enzyme found in pancreatic fluid that breaks down proteins. This enzyme is abnormal in hereditary pancreatitis.

life-threatening attacks that appear to last for weeks. The number of attacks is also quite variable. For example, severe attacks may occur three or four times in a year followed by a year without attacks.

Most episodes of pancreatitis resolve without problems. However, certain complications can arise that may worsen the condition and threaten the life of the patient. Because of the loss of large amounts of fluid into the abdomen, circulatory shock may occur. Shock occurs when fluid leaks from blood vessels, leaving an insufficient amount of blood volume to provide the body with the oxygen that it needs. Prolonged lack of appropriate levels of oxygen causes damage to many different organs of the body. If not immediately treated, shock can lead to death.

Another complication of pancreatitis is the development of a fluid collection that contains decaying products of an inflamed pancreas and other substances. This fluid collection is called a pseudocyst. A pseudocyst can become life threatening if it becomes infected (abscess) or if the fluid collection ruptures into the abdomen.

Other dangerous and life-threatening complications of pancreatitis include severe bleeding from the pancreas (hemorrhagic pancreatitis), higher risk for the formation of blood clots, and a higher risk of serious infections in the abdomen or damaged pancreas. In addition, people with hereditary pancreatitis have a much higher risk of developing pancreatic cancer for reasons that are not clear. Studies indicate that people with hereditary pancreatitis are at least 53 times more likely to develop pancreatic cancer than the general population and that 40%–75% of people with hereditary pancreatitis will develop pancreatic cancer by the age of 70. Pancreatic cancer is very difficult to treat and is nearly always fatal.

Over time, recurrent episodes of pancreatitis may leave the pancreas permanently damaged and unable to carry out its routine functions. The absence of digestive enzymes normally secreted by the pancreas results in poor digestion, chronic diarrhea, weight loss, and malnutrition (5%–45% of people), leaving a person generally weakened. The pancreas may also become unable to

QUESTIONS TO ASK YOUR DOCTOR

- How is pancreatitis inherited?
- What are the treatments for hereditary pancreatitis?
- What is my risk of developing pancreatic cancer?

secrete insulin in the bloodstream normally, creating imbalances in blood sugar and causing diabetes in 10%–25% of people with hereditary pancreatitis.

Diagnosis

Hereditary pancreatitis is diagnosed through a combination of medical history, physical examination, and laboratory testing. The onset of abdominal pain consistent with pancreatitis before the age of 20 in multiple family members without any other risk factor for pancreatitis (drinking large amounts of alcoholic beverages, gallstones) suggests a diagnosis of hereditary pancreatitis. The medical history and physical examination of these individuals during an episode of pancreatitis will show abdominal pain, nausea, vomiting, and abdominal swelling.

Diagnosis of pancreatitis can be made by noting high levels of pancreatic enzymes (amylase and lipase) circulating in the blood. Further abnormalities in the blood that suggest pancreatitis include increased white blood cells, changes in the blood substances that occur with dehydration and fluid loss, and decreases in calcium levels.

Other diagnostic methods can be used to track the progress of the disease and monitor for any complications. X-rays of the abdomen may show deposits of calcium that occur in 50% of cases of hereditary pancreatitis. Also, the intestines may show signs of inactivity because of the nearby inflammation. Computed tomography (CT) scans of the abdomen may reveal the inflammation of the pancreatitis and are very useful in monitoring for complications such as pseudocyst, infections, and bleeding.

Genetic testing allows for the definitive diagnosis of hereditary pancreatitis by identifying abnormalities in the trypsin gene. However, these tests are currently used only for research purposes and are not generally available.

Treatment and management

There is no cure for hereditary pancreatitis. The goals for treatment consist of pain control, establishing

alternate routes of feeding and fluid administration, and prevention or control of complications.

A person experiencing an episode of pancreatitis is nearly always admitted to the hospital for treatment. Since drinking or eating by mouth often worsens the patient's condition, alternative routes are needed. Large amounts of fluid are given by a small tube placed in a vein (intravenous or IV fluids) to replace the fluid that has leaked into the abdomen. This IV route can also be used to administer nutritional products and medications to relieve pain.

Fluids and acid that are produced by the stomach can worsen a patient's condition and increase pain. In order to drain these fluids, a small, flexible tube is inserted through the nose, down the throat, and into the stomach (nasogastric tube). The tube is then connected to a weak vacuum to remove the contents of the stomach. Complications may arise in the setting of pancreatitis. Bleeding may require administration of donor blood products by vein, while infections are treated using antibiotics also given by vein. Abscesses, large pseudocysts, or decaying portions of the pancreas may require drainage with a needle or may need to be removed surgically. People with a permanently damaged pancreas may require digestive enzyme supplements by mouth to assist with digestion and insulin injections to control diabetes.

People diagnosed with hereditary pancreatitis should be seen regularly by a team of healthcare professionals, including a primary-care physician, gastroenterologist, and medical geneticist. Individuals with this condition should refrain from drinking alcohol and avoid fatty foods. They may benefit from consultation with a licensed nutritionist.

Prognosis

Several systems have been developed to predict the outcome for people who are experiencing an episode of pancreatitis. The most widely used system utilized by health professionals is called "Ranson criteria," which utilizes a list of measurements that are determined during the first two days of the hospital stay.

In general, children who experience an episode of pancreatitis do well and are released from the hospital in three to five days. However, the development of any of the complications of pancreatitis worsens the prognosis and will likely result in a longer hospital stay. In the extreme, severe complications of pancreatitis can even lead to death.

Most people with hereditary pancreatitis will develop permanent damage to the pancreas as they grow older. Half of people will require surgery, and up to one-fourth will develop diabetes by the age of 70. Of even greater

concern, a significant percentage will develop pancreatic cancer, a diagnosis that is nearly always fatal within several years.

Hereditary spastic paraplegia

Definition

Hereditary spastic paraplegia (HSP) is not a single entity, but a group of clinically and genetically diverse hereditary degenerative disorders that have in common degeneration of the corticospinal tracts and posterior column tracts in the spinal cord. Patients with HSP consequently suffer from severe and progressive weakness and spasticity in the legs and feet. The corticospinal tracts are made of nerve fibers that convey motor information from the brain to the limbs. The posterior column carries sensory information regarding position sense from the arms and legs to the brain. The fibers that carry motor information to the legs are more often affected than those of the arms, resulting in progressive stiffness and

weakness of leg, thigh, calf, and lumbar spinal muscles. The age of onset, extent of degeneration, and severity of symptoms vary among affected people, even those in the same family. Some families show a pattern of disease called anticipation, with symptoms developing earlier in each new generation. In most individuals, however, the disease onset occurs between the second and the fourth decades of life.

Description

Dr. Adolf von Strümpell, a German neurologist, first described this disease in 1883. He was followed by Maurice Lorrain, a French physician, which explains why another name for HSP is Strümpell-Lorrain syndrome. Other names for this disorder are hereditary spastic paraparesis, Strümpell disease, familial spastic paraparesis, spastic spinal familial paralysis, hereditary Charcot disease, silver syndrome, French settlement disease, and Troyer syndrome. When the only manifested symptom is progressive spasticity, HSP is also known as pure hereditary spastic paraplegia.

People with early symptoms of HSP may notice only mild stiffness in the lower legs and some difficulties with their gait. As the disease progresses, they will require assistive devices like canes, walkers, or wheelchairs. They may also experience disturbances of urinary bladder function. Patients with complicated HSP develop such additional symptoms as cataracts and other visual disorders, epilepsy, deafness, ataxia, and dementia or other forms of cognitive impairment.

Genetic profile

There were over 76 genetic loci linked to different types of HSP as of 2015, and the mode of inheritance is known for 38: 18 types are inherited in an autosomal dominant pattern, 17 in an autosomal recessive pattern, and 3 in an X-linked pattern. The risk of an individual's inheriting an abnormal gene depends on the mode of transmission and whether the mutated gene is present on a sex chromosome or an autosome. Mutations in a number of different genes can result in a similar phenotype of HSP; this phenomenon is known as genetic heterogeneity. These genes are generically known as spastic paraplegia genes, or SPGs; 59 different SPGs had been identified as of 2015.

SPGs are thought to contain genetic information regarding proteins that help in microtubule formation and function. Some SPGs are known to code for such proteins as spastin and atlastin-1. Spastin helps to regulate the length of microtubules while atlastin-1 fuses microtubules together to form a network that makes up the endoplasmic reticulum of neurons (nerve cells). Microtubules combine

to form the protein framework of a nerve cell and their dysfunction leads to degeneration of the nerve cells. Other SPGs appear to be associated with mitochondrial dysfunction, leading to loss of protein quality.

HSP can be complicated when other neurological impairments are seen in addition to spasticity; or they may be uncomplicated. Uncomplicated or pure HSP is inherited as an autosomal dominant mutation in about 70% of cases, but the mutated gene varies from one family to another.

Autosomal dominant HSP

This is the most common form of HSP inheritance, with the mutated gene present on an autosome (non-sex chromosome). Only one copy of the abnormal gene is required to produce the disease. There is a 50% chance that an affected person will transmit the gene to an offspring. The disease can be present in both males and females; it can be transmitted from either the mother or the father to a son or a daughter, and there is usually an affected family member in each generation. Exceptions to the latter rule occur when the disease presented with very mild symptoms in earlier generations and was misdiagnosed as arthritis or walking difficulty due to old age. Also, the affected person might have died prior to manifesting full-blown symptoms. SPGs for autosomal dominant types of HSP have been identified on chromosomes 1p at 1p31.1 (gene presently unknown), 2p at 2p22.3 (the *SPAST* gene), 2p at 2p11.2 (the *REEP1* gene), 8q at 8q24.13 (the *KIAA0196* gene), 9q (gene presently unknown), 10q at 10q23.3 (gene presently unknown), 12q at 12q13.3 (the *KIF5A* gene), 14q at 14q22.1 (the *ATL1* gene), 15q at 15q11.2 (the *NIPA1* gene), 19q at 19q13.32 (the *RTN2* gene), and 20. In more than 50% of cases, the two most common gene mutations identified are on chromosome 2p and chromosome 14q, and are called the *spastin* and *atlastin-1* genes, or *SPAST* and *ATL1* genes. In complicated autosomal dominant HSP, one identified gene is on chromosome 10q. In a rarer form of infantile onset-ascending HSP, there is a deletion mutation in the *ALS2* gene at 2q33.1.

Autosomal recessive HSP

In autosomal recessive HSP, the mutant gene is present on an autosome. Two copies of the abnormal gene (one of maternal and one of paternal inheritance) are required for disease expression. Both males and females can express the disease and also transmit the abnormal gene. A mutant HSP gene that is recessive can be passed down silently for generations until someone finally inherits the recessive gene from both parents and develops the disorder. The parents of the affected person are called carriers, as they carry only one copy of the abnormal gene and do not express the disease. If a mother and father are

carriers for a recessive HSP gene mutation, each of their children has a 25% chance of developing HSP, a 50% chance of being a carrier, and a 25% chance of being normal. It is unlikely for individuals with autosomal recessive HSP to have children with the disorder, because their spouse would have to have the disorder or be a carrier. This possibility is more common in consanguineous marriages (i.e., marriage between cousins).

SPGs associated with this pattern of inheritance are located on chromosomes 2q at 2q37.3 (the *KIF1A* gene), 6q at 6q23 (gene currently unknown), 8p at 8p11.23 (the *ERLIN* gene), 8q at 8q12.3 (the *CYP7B1* gene), 10q at 10q22.1 (gene presently unknown), 13q at 13q14 (gene presently unknown), 13q at 13q13.3 (the *SPG20* gene), 14q at 14q22.1 (the *PAPLA1* gene), 15q at 15q21.1 (the *SPG11* gene), or the *SPG7* gene on 16q at 16q24.3. One form of autosomal recessive HSP, Troyer syndrome, is associated with the SPG on chromosome 13q.

X-linked HSP

X-linked HSP is a rare form in which the mutant genes are located on the X chromosome at Xq28, Xq11.2 (gene not currently known), Xq13.2 (the *SLC16A2* gene), or Xq22. Transmission is usually through the mother; the risk of inheriting this mutated gene and expressing the disease depends on the patient's gender. Women with an X-linked mutant HSP gene are generally not affected by the disorder; or if they are affected, they usually have less severe symptoms than males. Each son of a woman who is a carrier for X-linked HSP has a 50% chance of developing HSP. Each daughter of a woman who is a carrier for X-linked HSP has a 50% chance of being a carrier (female carriers of X-linked disorders often have no symptoms).

Sporadic HSP

In some instances, a definite mode of inheritance cannot be identified when there is no other affected family member. This difficulty can occur if the inheritance pattern has been autosomal recessive or X-linked, as it can skip generations, remain silent, and suddenly appear in the present generation. Also, the disease could have been milder (incomplete penetrance) and undiagnosed in prior generations; or the affected persons could have died prior to full symptom onset. Due to the phenomenon of anticipation, a child may exhibit symptoms even before the parent. Truly sporadic HSP is rare; it is caused by a new mutation occurring only in the affected individual.

Demographics

As usually happens with other rare neurological diseases, HSP symptoms may overlap or be mistaken for

KEY TERMS

Anticipation—A genetic phenomenon in which the symptoms of a disease appear at an earlier age in each successive generation.

Ataxia—Lack of coordination of voluntary muscle movements.

Atlastin-1—A protein encoded by the *ATL1* gene that is important in building and maintaining the structure of the endoplasmic reticulum in the nerve cells of the brain and spinal cord.

Autosome—Any chromosome that is not a sex chromosome.

Clonus—Involuntary rhythmic muscular contractions and relaxations.

Contracture—A tightening of muscles, usually near a joint, that prevents normal movement of the associated limb or other body part.

Endoplasmic reticulum—A network of flattened membranes and tubules within the cytoplasm of a cell that synthesizes and transports lipids (fats) and proteins.

Gait—A person's habitual pattern of walking, or the pattern of movement of his or her lower limbs.

Genetic heterogeneity—The production of apparently identical disorders by genes at different loci or by different genetic mechanisms.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Paraplegia—Impairment in the sensory or motor functions of the lower limbs.

Paresthesias—The medical term for prickling, burning, or “pins-and-needles” sensations.

Spasticity—Tightness, stiffness, increased muscle tone, or sustained involuntary contractions of the muscles.

Spastin—A protein encoded by the *SPAST* gene that regulates the length of microtubules and dissolves microtubule structures that are no longer needed.

Sporadic—Occurring randomly in the population with no known or apparent cause.

those of other neurodegenerative disorders. Consequently, HSP incidence is only estimated and is thought to be approximately 3 cases out of 100,000 individuals in the United States and Europe. Between 10,000 and

20,000 people in the United States are estimated to have this disease, of which about 10% have the complicated form of HSP. Ninety percent of HSP cases are uncomplicated and the patient's life expectancy is unaffected.

As far as is known, HSP occurs in all races and ethnic groups worldwide.

Signs and symptoms

Previously, HSP was classified into early-onset (type I) HSP and late-onset (type II) HSP. In type I, symptoms of spasticity occurred prior to age 35 but progressed slowly. In type II HSP, symptom onset occurred after age 35 with weakness, spasticity, mild sensory loss, and bladder problems, and the disease progressed faster. This classification is confusing as both early- and late-onset disease can occur in the same family due to the phenomenon of anticipation. Therefore, categorization into uncomplicated (pure) and complicated HSP is considered a more specific and useful distinction.

Uncomplicated HSP

Pure or uncomplicated HSP is usually inherited in an autosomal dominant pattern. It may start at any age, mostly in the second to fourth decades, but can also occur in infancy, early childhood, or old age. Mutations in the *ATL1* gene cause childhood-onset autosomal dominant HSP, also known as spastic paraplegia type 3A; and a defective *SPAST* gene causes the adult-onset form known as spastic paraplegia type 4. In children, the disease progresses until adolescence and then stabilizes, resulting in partial disability in walking. Complete paralysis of the legs is rare in uncomplicated HSP, regardless of age of onset.

Progressive difficulty walking is the main problem and occurs due to taut and weak muscles. This difficulty manifests initially as stumbling, stubbing the toe, catching the feet on uneven surfaces and sidewalks, clumsy gait, or difficulty with balance. The muscles that are most commonly affected include those on the inner side, front, and back of the thighs and calves, leading to difficulty with hip and ankle flexion. This distorted gait can lead to uncontrollable shaking (clonus) of the feet and scissoring of the legs while walking. Often the changes are so slowly progressive that patients do not notice subtle symptoms for several years. Arms are affected to a much lesser degree. Spasticity is worsened by cold, high humidity, emotional stress, and infections.

Other common symptoms include urinary urgency and frequency, hyperactive tendon reflexes, diminished vibration and position sense in the feet, leg paresthesias, muscle spasms, cramps, and pain. Muscles can atrophy at a late stage. High-arched feet (*pes cavus*) and bunions

QUESTIONS TO ASK YOUR DOCTOR

- How can you tell the difference between HSP and other conditions that resemble it?
- When should a person suspected of having HSP consider genetic testing?
- When should other family members be tested for HSP?
- Are there medications or treatments that will help to slow the progress of HSP?
- What resources are available for patients with HSP?

can occur due to imbalance in the strength and tone of muscles that maintain proper alignment of bones in the feet.

Complicated HSP

Complicated HSP is usually inherited in an autosomal recessive pattern with symptom onset between two and 16 years of age. Symptoms are progressive and may be associated with other neurological conditions, such as epilepsy, mental retardation, peripheral neuropathy, ocular degeneration such as retinopathy, and/or the destruction of the optic nerve. Other clinical complications are ataxia (loss of coordination), dysarthria (difficulty speaking), deafness, nystagmus (involuntary eye movements), decreased functioning of the adrenal glands, and ichthyosis (abnormal dryness, scaling, and thickening of the skin). However, these neurological symptoms may be caused by other disorders present at the same time. For instance, a person with uncomplicated HSP may have peripheral neuropathy due to diabetes.

Diagnosis

A detailed personal and family history along with physical and neurological examinations is the first tool in HSP diagnosis. The physician will conduct comparative examination of muscle tone and strength between arms and legs and look for signs of weakness in specific muscle groups of the thigh, presence of abnormal increase of deep tendon reflexes in the legs, loss of ankle flexibility, and decrease of sensation in the legs. A thorough clinical examination is vital to avoid misdiagnosing other conditions like vitamin B₁₂ deficiency, vitamin E deficiency, amyotrophic lateral sclerosis (ALS or Lou Gehrig's disease), and tropical spastic paraparesis, all of which mimic HSP.

Genetic screening for various SPGs is the definitive test to avoid misdiagnosis and is commercially available. The University of Michigan Neurogenetic Disorders Clinic is the largest clinical and research program for HSP in the United States, and one of the few that offers comprehensive evaluation, including genetic testing. As of 2015, there were several laboratories in the United States and Europe that offered molecular genetic testing for panels of genes associated with HSP; the number of genes tested in these panels ranged from 10 to 40 different genes. Other ancillary tests like nerve conduction studies, spinal tap, magnetic resonance imaging (MRI), and blood tests help to exclude some of the other mimickers of the disease.

Treatment and management

There was no curative or preventive treatment for HSP as of 2015. Symptomatic treatment for muscle spasm and spasticity includes oral medications like baclofen, tizanidine, and benzodiazepines like diazepam to relax muscles and decrease the intensity of spasms. Major side effects from these drugs include confusion, dry mouth, drowsiness, and sedation. Symptomatic treatment for painful neuropathy includes medications like gabapentin and the selective serotonin reuptake inhibitors (SSRIs) or the tricyclic antidepressants. Medications like oxybutynin can help in treating an overactive bladder. Baclofen can also be administered through a mechanical pump implanted in the space around the spinal cord to minimize systemic adverse effects.

Newer approaches involve the local injection of botulinum toxin (Botox) into the spastic muscles to reduce muscle hyperactivity; the effect tends to last three to six months after an injection. Surgery may be necessary to relieve tendon contractures and to lengthen spastic muscles. An electrical stimulator device implanted in the nerves near the tailbone can help in stimulating the bladder for complete urinary evacuation. A newer medication being tried for treatment of HSP is dalfampridine (Ampyra), a drug used in the United States since 2010 for the treatment of multiple sclerosis.

Supportive care includes physical therapy, which helps to improve muscle strength and range of motion, and prevent joint contractures and bedsores. Therapies may include stretching, strengthening and aerobic exercises, balance and coordination training, gait training (including a new approach that uses robots as gait trainers), and appropriate use of such assistive devices as canes, braces, and walkers. Treatments can also include such techniques as massage, ultrasound, electrical stimulation, or whirlpool treatments. Exercise also enhances the patient's sense of well-being and reduces stress and depression.

Prognosis

The prognosis of HSP varies widely, but most often it is compatible with a normal life expectancy. The rate of progression varies considerably and is influenced by the mode of inheritance. Some patients have serious disability not only from the spasticity but also from associated neurological problems. Others have very mild disability and can lead a very productive and almost normal life. Complications arising from falls and immobility, however, may inadvertently shorten a patient's life.

Hereditary spherocytosis

Definition

Hereditary spherocytosis (HS) is a relatively common and highly variable inherited disorder of the red blood cells. In HS, red blood cells become sphere-shaped instead of the usual biconcave (hourglass) shape. The hourglass shape is vital for the blood cells to function—it offers increased surface area so that oxygen

and carbon dioxide can diffuse more easily through the cell's tissue, and the shape lets the cells circulate more easily in tight places, like small capillaries. These spherocytes are broken down more quickly than normal red blood cells, resulting in anemia and related complications.

Description

Hereditary spherocytosis results from a molecular change in one of the proteins making up the cytoskeleton of the red blood cell, which consists of the network of proteins that support and maintain the integrity of the red cell membrane. Genetic mutations in membrane proteins lead to loss of these and related membrane components. As the membrane becomes unstable, and the surface area of the membrane decreases, spherocytes form. The spleen provides an environment that encourages spherocyte breakdown. Due to their increased rigidity, spherocytes tend to become trapped in the spleen and then broken down by macrophages, which are specialized white blood cells. This hemolytic process most often leads to mild, chronic anemia. Depending in part on the particular genetic mutation underlying HS in a given individual, anemia can be severe and can require chronic blood transfusions. Additional complications related to anemia can arise.

Genetic profile

About 75% of all cases of HS are due to the presence of an autosomal dominant mutation, one in which the mutated gene is passed on from either parent. Most of these cases result from the inheritance of a mutation from one parent, but one in four of these cases is sporadic and due to a new mutation that has occurred in the affected individual. A minority of cases of HS are recessively inherited. HS-causing mutations have been described in four genes, each of which codes for a protein involved in maintaining stability of the red blood cell membrane. The cytoskeleton can be thought of as a "scaffolding" or "frame" that is attached to and maintains the "wall" that is the cell membrane. The red blood cell membrane is made up of lipids, which are fat and fat-like molecules, and proteins called integral membrane proteins. The cytoskeleton lies just below the cell membrane and is made up of additional proteins, including spectrin, ankyrin, protein 4.1, and others.

Ankyrin

The ankyrin gene is located on the short arm of chromosome 8 (8p11.2). A total of 34 mutations in the ankyrin gene have been associated with HS. These account for 35% to 65% of all HS cases, including both

Light micrograph showing the abnormal round convex blood cell of hereditary spherocytosis. (Biophoto Associates/Science Source)

dominant and recessive forms. Dominant-acting mutations tend to be those that result in a shortened ankyrin protein, including so-called frameshift and nonsense mutations. Recessive-acting mutations tend to be those that result in subtler changes to the protein. These include so-called missense mutations, which result in the substitution of a single amino acid—the building block of proteins—which can have an effect on protein function. Recessive mutations also include those in the area “upstream” from the gene, in the promoter region that helps to determine the quantity of protein made from the gene. Rarely, spherocytosis can be one symptom within a larger syndrome that is due to a deletion of a portion of chromosome 8. Such a microdeletion syndrome can affect several genes, including the ankyrin gene, and there can be a range of physical and mental effects.

Spectrin

Spectrin is a cytoskeleton protein made of two components: alpha spectrin and beta spectrin. Two recessive mutations have been identified in the alpha spectrin gene on chromosome 1. This recessive form of the disease tends to have relatively severe hemolytic anemia. Nineteen mutations have been described in the beta spectrin gene on chromosome 14. These result in dominantly inherited HS.

Band 3 and others

Mutations in the gene for band 3, an integral membrane protein, account for 15% to 25% of all cases of HS. Five dominant mutations have been described, most of which result in a shortened protein. Disease-causing mutations in other cytoskeleton or red cell membrane proteins are rare but have been described.

Modifying genetic factors

Disease severity is affected not only by the nature of the primary genetic mutation but also by other genetic variations. Individuals with HS who also have Gilbert syndrome have an increased risk of gallstones. Gilbert syndrome is caused by a change in the UGT 1A1 gene that results in increased levels of bilirubin. Researchers have also hypothesized that persons with other inherited or acquired forms of hemolytic anemia may also be at increased risk of gallstones if they have a disease-causing HS mutation. The presence of hereditary hemochromatosis in addition to HS increases the propensity toward iron overload. Hereditary hemochromatosis is a relatively common recessive condition that can lead to organ failure due to iron overload if untreated.

Demographics

HS has been seen in individuals of many ethnic backgrounds but is particularly common among people of northern European backgrounds, affecting about one in 2,000 of such individuals.

Signs and symptoms

Symptoms of HS can be extremely variable. Some individuals may experience onset as early as the neonatal period and require treatment. Others may have only mild anemia that does not require treatment and does not become evident until later in life. Some individuals with few and subtle signs may even go undiagnosed. Variability is largely influenced by the primary underlying genetic mutation, with the recessive forms of the disease tending to be most severe. This does not account for all of the variability, however, given that multiple affected individuals within the same family who carry the same genetic mutation may have symptoms of varying severity. The effects of modifying genes or environmental factors may contribute to this additional variability.

Anemia

The red blood cell membrane has increased fragility in HS. Therefore, red cells are more easily broken down, a symptom called hemolytic anemia, which occurs primarily in the spleen. The spleen filters out old and abnormal red blood cells and fights infection from bacteria, particularly the encapsulated type. Anemia can be unnoticeable or mild, or it can be rapid and severe. Rapid, acute breakdown of red blood cells can occur as a result of exposure to chemicals or medications that are known to further increase red blood cell membrane fragility. It can also occur as a result of infection that increases the hemolytic activity of the spleen or decreases red blood cell production. Acute aplastic anemia events, in which red

KEY TERMS

Anemia—A blood condition in which the level of hemoglobin or the number of red blood cells falls below normal values. Common symptoms include paleness, fatigue, and shortness of breath.

Bilirubin—A yellow pigment that is the end result of hemoglobin breakdown. This pigment is metabolized in the liver and excreted from the body through the bile. Bloodstream levels are normally low; however, extensive red blood cell destruction leads to excessive bilirubin formation and jaundice.

Cytoskeleton—The network of proteins underlying and maintaining the integrity of the red blood cell membrane.

Encapsulated—Referring to bacteria that have a thick capsule protecting their cell wall.

Hemochromatosis—Accumulation of large amounts of iron in the tissues of the body.

Hemoglobin—A protein-iron compound in the blood that carries oxygen to the cells and carries carbon dioxide away from the cells.

Hemolytic—Refers to the type of anemia caused by the breakdown of red blood cells, as compared to anemia due to decreased production, for example.

Macrophage—Specialized white blood cells that play a role in breaking down old or abnormal red blood cells.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Red blood cell—A hemoglobin-containing blood cell that transports oxygen from the lungs to tissues. In the tissues, the red blood cells exchange their oxygen for carbon dioxide, which is brought back to the lungs to be exhaled.

Reticulocyte—Immature red blood cells.

Spherocytes—Red blood cells that are spherical in shape, as compared to the normal biconcave shape. Spherocytes are more rigid, and their membranes are more fragile than normally shaped red blood cells.

Spleen—An organ located in the upper abdominal cavity that filters out old red blood cells and helps fight bacterial infections. It is responsible for breaking down spherocytes at a rapid rate.

blood cell production halts, can occur with deficient folate levels or following infection by a specific virus called parvovirus.

According to a recent study by Yale physicians, a novel mutation in the gene that encodes alpha-spectrin, a protein that is essential for normal red blood cell membranes, is responsible for many cases of recessive hereditary spherocytosis (rHS), the most severe form of the disease. Alpha-spectrin provides both strength and flexibility to red blood cell membranes, helping cells maintain their shape and integrity while making their circuit through the body. Cells without sufficient alpha-spectrin in their membranes suffer membrane damage and will lose strength and flexibility. These damaged, alpha-spectrin-deficient red blood cells are then trapped and destroyed by the spleen. The excessive removal of damaged red blood cells leads to anemia, which in some cases is life-threatening. The clinical implication for this finding is that it will update commercially available diagnostic gene panels used to screen DNA for HS mutations. These improved gene panels can assist providers in selecting the most effective treatment options, as splenectomy sometimes fails in patients with rHS, who may

instead require a hematopoietic stem cell transplant. Finally, better gene panels will allow for more accurate genetic counseling for prospective parents with family histories of HS.

Jaundice

Jaundice occurs when the level of bilirubin, a breakdown product of hemoglobin, increases. As red blood cells break down rapidly, the liver may not be able to keep up with the increased need to metabolize bilirubin, which can deposit in the skin and eyes, causing a yellowish discoloration.

Gallstones

Bilirubin levels can also be increased in the bile, which is the fluid secreted by the liver into the intestine. Bile reaches the intestine by passing through the gallbladder and bile duct. Excess bilirubin can form stones in the gallbladder early in life.

Hemochromatosis

Hemochromatosis, or high iron levels, is characteristic of HS. Iron overload can lead to dysfunction of organ

QUESTIONS TO ASK YOUR DOCTOR

- If I suspect that hereditary spherocytosis may be somewhat common in our family, should I see a genetic counselor about being tested for the disorder?
- Under what circumstances would a splenectomy be indicated for the treatment of hereditary spherocytosis?
- What is the prognosis for hereditary spherocytosis?
- Is it necessary for a person with hereditary spherocytosis to monitor the status of his or her disease on a regular basis, and if so, what kind of tests or treatments are recommended?

systems, including the endocrine system, which directs hormone levels.

Other complications

Leg ulcers are seen in HS, and acute kidney failure due to hemolytic anemia is a rare complication. Rarely, HS can be seen within a syndrome as one symptom in combination with other complications such as neurological problems and other congenital physical differences. Such syndromes may be caused by the deletion of a portion of a chromosome including a gene known to be associated with HS, among other genes.

Diagnosis

HS must be distinguished from other causes of hemolytic anemia that can resemble HS. These include immune hemolytic anemia, G6PD deficiency, unstable hemoglobin traits or diseases, Wilson disease, and spherocytosis due to burn injury or toxin exposure (e.g., clostridia—bee, spider, or snake venom). Routine blood tests are typically sufficient to diagnose HS, particularly if an individual is showing symptoms. A peripheral blood smear, which is a slide preparation of a blood sample, will show the presence of a number of spherocytes that are uniform in appearance. Bilirubin levels tend to be elevated. A complete blood count will show several abnormalities. Hemoglobin levels tend to be decreased. Reticulocytes, which are immature red blood cells, tend to be increased. Red blood cells tend to be smaller than normal, marked by a decreased mean cell volume (MCV). The mean cell hemoglobin concentration (MCHC) tends to be high, which is a reflection of the

overall decrease in the cell volume. Ektacytometry is a specialized test that can demonstrate the fragility of the red blood cell membrane by placing the cells under stress and identifying increased levels and specific patterns of hemolysis. Another specialized test, called the rapid flow cytometric test, has recently been developed. This test can determine differences in fluorescent staining patterns that distinguish normal red blood cells from those that are characteristic of HS. It is highly sensitive and specific for HS and should aid in its rapid diagnosis.

Treatment and management

Most individuals with HS do not have symptoms that are severe enough to require treatment. For those with the more severe forms, blood transfusion therapy can effectively improve symptoms until a child is old enough for total or partial removal of the spleen, the organ responsible for most of the red blood cell destruction. Splenectomy most often eliminates HS complications. Some risk remains for ongoing chronic anemia or acute anemic events, particularly those caused by viruses and other factors that can temporarily halt red blood cell production. Splenectomy can lead to an increased risk for blood clots as well as life-threatening bacterial infection, given the spleen's role in fighting bacterial infections. Studies have shown that partial, as distinguished from total, splenectomy can be effective at ameliorating HS symptoms while also maintaining the bacterial-fighting capacity of the spleen and decreasing the chance for blood clots. Prophylactic antibiotics (e.g., penicillin) and additional vaccinations for common bacterial infections play roles in decreasing negative side effects of partial or total splenectomy. Surgery may be needed to remove gallstones that become symptomatic, which usually will not occur until after age 10.

Prognosis

Prognosis is very good for all types of HS, particularly the milder forms. Treatment is very effective for the more severe forms. There are only a small number of affected individuals who still experience anemia and other symptoms following splenectomy.

Hermansky-Pudlak syndrome

Definition

Hermansky-Pudlak syndrome (HPS) is a rare inherited disorder of melanin production. Melanin is the pigment that gives color to the skin, hair, and eyes. A lack or decrease of pigment in the skin and eyes is called oculocutaneous albinism. HPS is a specific type of oculocutaneous albinism that includes a bleeding tendency and the storage of ceroid, the by-product of cell membrane breakdown, in the body’s cells.

Description

In 1959, Drs. F. Hermansky and P. Pudlak reported two unrelated people with oculocutaneous albinism who had lifelong bleeding problems. The female died at age

33, and at that time large amounts of pigment were discovered in the walls of her small blood vessels.

Genetic profile

HPS is an autosomal recessive disorder. This means that the disease manifests itself when a person has inherited one nonworking copy of the *HPS* gene from each parent. Parents who carry the gene for HPS are healthy and have typical skin pigmentation. However, each time they have a child, the chance for the child to have HPS is 25%, or 1 in 4. Unless someone in the family has HPS, most couples are unaware of their risk.

Researchers mapped the *HPS1* gene to the long arm of chromosome 10 in 1995 and identified its exact location in 1996. The protein produced by the *HPS* gene helps organelles (specialized parts) of the cell’s cytoplasm (portion of the cell between the membrane and nucleus) to develop and function normally.

In 1999, another group of researchers identified a mutation, or gene change, in the *AP3B1* gene located on chromosome 5 as another cause of HPS. This gene makes AP3, a molecule that helps to sort proteins within the body’s cells.

As of 2014, at least nine genes had been identified as being associated with HPS, all of which code for proteins associated with the movement and function of lysosome-related organelles (LRO), which are complexes involved in producing melanocytes, platelets, and lung cells. The nine genes affected are *HPS1*, *HPS3–HPS6*, *AP3B1*, *BLOC1S3*, *BLOC1S6*, and *DTNBP1*, all of which play a role in the structure and function of LRO, and three of which are associated with pulmonary fibrosis (a lung disease). The variations of signs and symptoms of the genes affected are widespread, and a 2013 study even determined that a mutation of the *HPS4* gene has a clinical correlation with schizophrenia. Another study associated a gene mutation of *AP3B1* with lymphoma.

Demographics

In northwest Puerto Rico, HPS is a common inherited disorder, 75% of cases of which are linked to a mutation in the *HPS1* gene and 25% of cases of which are linked to a mutation in the *HPS3* gene. More than 300 persons are affected. The carrier rate is about 1 in 21. Intermarriage accounts for the high frequency. Researchers have traced the origin of HPS to southern Spain. Cases have also been reported in the Dutch, Swiss, and Japanese. Both sexes are equally affected. However, females have more lung symptoms than males. Throughout the rest of the world, 45% of cases have mutations in *HPS1*, 20% in *HPS3*, and the remaining 35% associated with the other seven identified genes affiliated with HPS.

A woman, who suffers from albinism, holds her daughter at her parents' home in Puerto Rico. Puerto Rico has one of the world's highest rates of Type 1 Hermansky-Pudlak syndrome, a rare and fatal form of albinism that causes a deadly lung disease. (AP Images/Brennan Linsley)

Signs and symptoms

People with HPS have a broad range of skin color from tan to white, reflecting the partial absence of pigmentation. Hair color ranges from brown to white, reflecting how much pigmentation is present.

Poor vision and eye abnormalities are common in people with HPS. Visual acuity can approach 20/200. Nystagmus, an irregular rapid back-and-forth movement of the eyes, is also common. The eyes can have an improper muscle balance called strabismus. Sensitivity to bright light and glare, known as photophobia, is a frequent complaint of people with HPS. These visual problems all result from abnormal development of the eye due to the lack of pigment. Just as skin and hair color vary, so will eye color. Red, brown, hazel, and violet eyes have been reported.

A bleeding tendency distinguishes HPS from other types of albinism. People with HPS bruise easily and bleed for an extended time after dental extractions and surgical procedures. Platelets are the disc-shaped structures in the blood that cause clotting. In people with

HPS, the platelets are missing certain internal components that cause them to clump together during the clotting process.

The third finding of HPS is the accumulation of ceroid in certain cells of the body such as bone marrow and the lung. As ceroid collects in the lungs, it makes the affected individual prone to respiratory infections and progressive lung disease that restricts breathing. Some people also complain of colitis (an inflammation of the colon) and diarrhea (loose, watery stools).

Diagnosis

Diagnosis of HPS can be made by specialized platelet testing and molecular testing for the known gene mutations. Very few laboratories are equipped to perform these tests. A person who is suspected to have HPS should consult with a geneticist or genetic counselor to arrange for the appropriate tests. Molecular testing is available for Puerto Rican families who usually have a specific detectable gene alteration, which is a duplication of a small segment of the gene.

KEY TERMS

Bioptics—Glasses that have small telescopes fitted in the lens.

Ceroid—The by-product of cell membrane breakdown.

Colitis—Inflammation of the colon.

Cytoplasm—The substance within a cell, including the organelles and the fluid surrounding the nucleus.

Diarrhea—Loose, watery stool.

Melanin—Pigments normally produced by the body that give color to the skin and hair.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Nystagmus—Involuntary, rhythmic movement of the eye.

Oculocutaneous albinism—Inherited lack of pigment in the skin, eyes, and hair.

Organelle—Small, subcellular structures that carry out different functions necessary for cellular survival and proper cellular functioning.

Photophobia—An extreme sensitivity to light.

Sputum—A mixture of saliva and mucus from the lungs.

Strabismus—An improper muscle balance of the ocular muscles resulting in crossed or divergent eyes.

Analysis of the person's platelets will determine if he or she is lacking the critical internal parts, called dense bodies, that help to clot blood. If dense bodies are not present, then HPS is the diagnosis.

For affected people of Puerto Rican ancestry, one unique gene mutation is present. Several other mutations can also be detected, but the lack of a gene mutation does not mean a person does not have HPS, since all mutations have not been identified.

For some families with an affected child, prenatal diagnosis may be possible for future pregnancies. Parents should consult with a genetics specialist when planning a pregnancy.

Treatment and management

For the individual with HPS, vision problems are always present. Many people will meet the legal

QUESTIONS TO ASK YOUR DOCTOR

- What are the chances that I will go completely blind?
- How can I prevent future eye or skin damage?
- How often should I be evaluated for lung disease, and what are the early symptoms of it?
- What is the maximum amount of time I should spend in the sun?
- Are there any pharmaceuticals I can take to help me with my blood clotting?

definition of blindness but still have enough vision for reading and other activities. Other affected people may be farsighted or nearsighted.

An ophthalmologist, a specialist for the eyes, can help those individuals who have strabismus, a muscle imbalance in the eyes. They can have corrective surgery that will not only improve their physical appearance but also expand their visual field. Surgery cannot restore pigment to the eyes or correct the optic nerve pathways leading from the brain to the eyes.

Many optical aids can help a person with HPS function better in daily life. Aids like hand-held magnifiers, strong reading glasses, and glasses that have small telescopes fitted in the lens called bioptics can make hobbies, jobs, and other activities easier.

Protection from excessive sunlight is crucial for people with HPS. Sunscreens of the highest rating should be used to decrease the chance for fatal skin cancers. By wearing clothing that blocks as much sunlight as possible, people with HPS can enjoy outdoor activities. A dermatologist, a specialist in skin disorders, can examine the affected person if any changes in skin color or appearance occur. Annual skin check-ups are important.

As people with HPS reach their 30s, they begin to develop lung disease. The first sign is difficulty in breathing, followed by a cough that does not bring up sputum, a mixture of saliva and mucus, from the lungs. Gradually, the lungs develop a tough, fibrous tissue that further limits breathing. The inability to breathe is the most common cause of death for people with HPS. A lung transplant may be an option for a person with end-stage lung disease.

Prolonged bleeding after tooth extraction, nosebleed, or surgery occurs regularly in people with HPS. Before any surgery, treatment with desmopressin, a drug that

stimulates clotting activity, can be effective. Individuals with HPS should avoid aspirin because it makes blood less likely to clot.

Prognosis

Many people with HPS may have concerns about their physical appearance and decreased vision. Education about the disorder is important to prevent isolation and stigmatization. Once the visual difficulties are addressed, people with albinism can participate in most activities.

Although many preventive efforts can improve the quality of life for a person with HPS, the progressive lung disease cannot be halted. The inability to breathe generally becomes fatal when the affected person is 40–50 years old.

Tangier disease

Hirschsprung disease

Definition

Hirschsprung disease, also known as congenital megacolon or aganglionic megacolon, is an abnormality in which certain nerve fibers are absent in segments of the bowel, resulting in severe bowel obstruction.

Description

Hirschsprung disease is caused when certain nerve cells (called parasympathetic ganglion cells) in the wall of the large intestine (colon) do not develop before birth. Without these nerves, the affected segment of the colon lacks the ability to relax and move bowel contents along. This condition is referred to as “aganglionosis,” and it causes a constriction in a segment of the bowel. The section above the constricted area dilates due to stool becoming trapped, producing megacolon (dilation of the colon). The disease can affect varying lengths of bowel segment, most often involving the region around the rectum. In up to 10% of children, however, the entire colon and part of the small intestine are involved. The length of the affected intestine accordingly classifies the disease: The most common form of the disease (approximately 80% of patients) is called short-segment Hirschsprung disease (S-HSCR), where the aganglionosis does not extend beyond the sigmoid colon. Approximately 20% of the patients are diagnosed with the long-segment variant (L-HSCR), in which the aganglionosis extends further.

Genetic profile

There is a variety of evidence showing that Hirschsprung disease is caused by genetic factors. Hirschsprung disease occurs early in fetal development when there is either failure of ganglion cell development, failure of nerve cell migration, or arrest in nerve cell development in a segment of bowel. The absence of these nerve fibers, which help control the movement of bowel contents, is what results in intestinal obstruction accompanied by other symptoms.

A complex genetic pattern is emerging and mutations in at least eight different genes have been implicated in causing Hirschsprung disease. The genes are *RET*, *GNDF*, *NRTN*, *EDNRB*, *EDN3*, *ECE1*, *SOX10*, and *ZFHX1B/SMADIP*; they are thought to be important for the healthy development of the gut. When they are not working correctly, it may lead to disease. For example, the *RET* gene codes for producing a protein that is involved in signaling within cells. This protein appears to be essential for the normal development of several

KEY TERMS

Aganglionosis—Section of bowel in which the normal enteric nerves are absent.

Anus—The opening at the end of the intestine that carries waste out of the body.

Barium enema x-ray—A procedure that involves the administration of barium into the intestines by a tube inserted into the rectum. Barium is a chalky substance that enhances the visualization of the gastrointestinal tract on x-ray.

Chromosomal deletion—Loss of a segment of DNA from a chromosome.

Colostomy—The creation of an artificial opening into the colon through the skin for the purpose of removing bodily waste. Colostomies are usually required because key portions of the intestine have been removed.

Down syndrome—Chromosomal disorder caused by the presence of all or part of an extra chromosome 21.

Endoscopic mucosal resection—Removal of the mucosa during endoscopy.

Enterocolitis—Severe inflammation of the intestines that affects the intestinal lining, muscle, nerves, and blood vessels.

Manometry—A balloon study of internal anal sphincter pressure and relaxation.

Meconium—The first waste products to be discharged from the body in a newborn infant, usually greenish in color and consisting of mucus, bile, and so forth.

Megacolon—Dilation of the colon.

Mucosa—Mucus-secreting membrane lining all body cavities or passages that communicate with the exterior.

Parasympathetic ganglion cell—Type of nerve cell normally found in the wall of the colon.

Rectal suction biopsy—The removal and examination of a sample of rectum tissue for diagnostic purposes.

kinds of nerve cells, including nerves in the intestine. *RET* mutations result in a nonfunctional version of the *RET* protein that cannot interact with growth factors or transmit signals within cells. Without *RET* signaling, enteric nerves do not develop properly. Because these nerves control contractions that move stool through the

intestine, their absence leads to the intestinal symptoms of Hirschsprung disease. The pattern of inheritance for L-HSCR is autosomal dominant whereas the inheritance of the much more common S-HSCR is believed to be multifactorial.

A chromosomal abnormality is present in approximately 12% of individuals with Hirschsprung disease. The most common chromosomal abnormality associated with the disease is Down syndrome (trisomy 21), which occurs in 2%–10% of all individuals with Hirschsprung disease. Although individuals with Down syndrome are at a 100-fold higher risk for Hirschsprung disease than the general population, none of the identified Hirschsprung single genes reside on chromosome 21; thus, the association between Down syndrome and Hirschsprung disease remains unknown. Other chromosomal abnormalities associated with Hirschsprung disease include deletions that encompass Hirschsprung-associated genes. For example, del13q22 (*EDNRB*), del10q11.2 (*RET*), and del2q22 (*ZFHX1B*) have been identified.

Demographics

The overall incidence of Hirschsprung disease in the United States is about 1 in about 5,000 live births. The incidence varies significantly among ethnic groups with 1.0, 1.5, 2.1, and 2.8 per 10,000 live births in Hispanics, Caucasian Americans, African Americans, and Asians, respectively. It is about four to five times more common in males than in females. Prevalence may also vary by region and has been shown to be as high as 1 per 3,000 live births in the Federated States of Micronesia. Nearly all children with Hirschsprung disease are diagnosed before age two. Approximately 50% of children affected with this disease are diagnosed before age one. A small number of children with Hirschsprung disease are not diagnosed until much later in childhood or adulthood.

Signs and symptoms

The initial symptom is usually severe, continuous constipation. A newborn may fail to pass meconium (the first stool) within 24 hours of birth, may repeatedly vomit yellow- or green-colored bile, and may have a distended (swollen, uncomfortable) abdomen. Occasionally, infants may have only mild or intermittent constipation, often with diarrhea.

While two-thirds of cases are diagnosed in the first three months of life, Hirschsprung disease may be diagnosed later in infancy or childhood. Occasionally, even adults are diagnosed with a variation of the disease. In older infants, symptoms and signs may include anorexia (lack of appetite or inability to eat), lack of the urge to move the bowels or empty the rectum on physical

QUESTIONS TO ASK YOUR DOCTOR

- What are the signs and symptoms of Hirschsprung disease, and how is the condition distinguished from other kinds of bowel disease?
- At what point after diagnosis for Hirschsprung disease should surgery be considered for our child?
- What portion of the child's bowel is affected by the disorder, and how does this affect the program of treatment planned for our child?

examination, distended abdomen, and a mass in the colon that can be felt by the physician during examination. It should be suspected in older children with abnormal bowel habits, especially a history of constipation dating back to infancy and ribbon-like stools.

Occasionally, the presenting symptom may be a severe intestinal infection called enterocolitis, which is life threatening. The symptoms are usually explosive, watery stools and fever in a very ill-appearing infant. It is important to diagnose the condition before the intestinal obstruction causes an overgrowth of bacteria that evolves into a medical emergency. Enterocolitis can lead to severe diarrhea and massive fluid loss, which can cause death from dehydration unless surgery is done immediately to relieve the obstruction.

Diagnosis

Hirschsprung disease in the newborn must be distinguished from other causes of intestinal obstruction. The diagnosis is suspected by the child's medical history and physical examination, especially the rectal exam. The diagnosis can be confirmed by a barium enema x-ray, an imaging technique that shows a picture of the bowel. The x-ray will indicate if a segment of bowel is constricted, causing dilation and obstruction. A rectal suction biopsy can also be performed. In this technique, a small piece of the lining of the rectum is taken off. Then this tissue is looked at very closely under a microscope (biopsy) to see if it is normal. Rectal suction biopsy is done using a tube the size of a rectal thermometer. Adults may also undergo manometry, a balloon study (device used to enlarge the anus for the procedure) of internal anal sphincter pressure and relaxation.

Treatment and management

Hirschsprung disease is first treated by rectal irrigation to decrease bowel distention. Eventually, surgery is

performed to remove the diseased, nonfunctioning segment of the bowel and restore bowel function. This is often done in two stages. The first stage relieves the intestinal obstruction by performing a colostomy. This is the creation of an opening in the abdomen (stoma) through which bowel contents can be discharged into a waste bag. When the child's weight, age, or condition is deemed appropriate, surgeons close the stoma, remove the diseased portion of bowel, and perform a "pull-through" procedure, which repairs the colon by connecting functional bowel to the anus. This usually establishes fairly normal bowel function. Hirschsprung disease is a congenital abnormality that has no known means of prevention. It is important to diagnose the condition early in order to prevent the development of enterocolitis. Genetic counseling can be offered to a couple with a previous child with the disease or to an affected individual considering pregnancy to discuss recurrence risks and treatment options. Prenatal diagnosis is not available.

Clinical trials

A few clinical trials on Hirschsprung disease are currently sponsored by the National Institutes of Health (NIH) and other agencies. In 2015, the NIH reported 15 recruiting, active, or completed studies. These included the three following recruiting studies:

- The identification of genetic, immunologic, and microbial markers of Hirschsprung-associated enterocolitis in children with Hirschsprung disease (HAEC). (NCT02193685)
- A genetic study of Hirschsprung disease. (NCT00478712)
- A study of genetic mosaicism in Hirschsprung's disease. (NCT01927809)

Clinical trial information is constantly updated by the NIH and the most recent information on Hirschsprung disease trials can be found at <http://www.clinicaltrials.gov>

Prognosis

Without recognition and treatment, there is a 50% mortality rate for Hirschsprung disease. Overall, an early diagnosis results in the best prognosis, with a 2.4% mortality rate after surgery (0.5% after colostomy), resulting from complications. Most infants with Hirschsprung disease achieve good bowel control after surgery, but a small percentage of children may have lingering problems with soilage or constipation. These infants are also at higher risk for an overgrowth of bacteria in the intestines, including subsequent episodes of enterocolitis, and should be closely followed by a physician.

Holoprosencephaly

Definition

Holoprosencephaly is a disorder in which there is a failure of the front part of the brain to properly separate into what is commonly known as the right and left half of the brain. This lack of separation is often accompanied by abnormalities of the face and skull. Holoprosencephaly may occur individually or as a component of a larger disorder.

Description

Types of holoprosencephaly

There are three different types of holoprosencephaly: alobar, semilobar, and lobar. Each of these classifications is based on the amount of separation between what is commonly known as the left and right halves of the brain. Alobar holoprosencephaly is considered to be the most severe form of the disease, in which the separation between the two halves, or hemispheres, completely fails to develop. Semilobar holoprosencephaly represents holoprosencephaly of the moderate type, in which some separation between the hemispheres has occurred. Lobar holoprosencephaly represents the least severe type of holoprosencephaly, in which the hemispheres are almost, but not completely, divided.

The severity of the effect of the disease on the brain is often reflected in craniofacial abnormalities (abnormalities of the face and skull). This has led to many health-care professionals utilizing the phrase "the face predicts the brain." This phrase is generally, but not always, accurate. Children may have severe craniofacial abnormalities with mild (lobar) holoprosencephaly, or children may have severe (alobar) holoprosencephaly with mild facial changes. Since the development of the face, skull, and the front of the brain are interconnected, the changes in the face often, but do not always, correspond with changes in the brain. Finally, the designation of these disorders from least severe to most severe can be mildly misleading, since the best predictor of the severity of the disease, is how well the brain functions, not its appearance. The alobar, semilobar, and lobar categories are universally utilized and give an indication of the severity of the disease, so knowledge of these categories and what they represent is useful.

Other brain abnormalities in holoprosencephaly

All patients with holoprosencephaly lack a sense of smell through the first cranial nerve (the olfactory nerve). Interestingly enough, one has a partial sense of smell through the sense of taste, which is governed by the seventh cranial nerve. The term "smell" and what it means in a conventional and strictly neurological sense differ, so it may be useful to think of persons with holoprosencephaly as lacking a portion of what is commonly referred to as "smell." This deficiency in smell can be detected by testing. One other important structural abnormality should be mentioned. The corpus callosum, which is the part of the brain that connects the right and left hemispheres with each other, is absent or deficient in persons with holoprosencephaly.

Synonyms for holoprosencephaly

Arrhinencephaly and familial alobar holoprosencephaly are synonyms for this disorder.

MRI of a 20-month-old girl with holoprosencephaly. The dark area represents the abnormally large fluid-filled ventricle typical of this disorder. (SPL/Science Source)

Genetic profile

Genetic causes of holoprosencephaly

Holoprosencephaly is a feature frequently found in many different syndromes including, but not limited to, trisomy 13, trisomy 18, triploidy, pseudotrisomy 13, Smith-Lemli-Opitz syndrome, Pallister-Hall syndrome, Fryns syndrome, CHARGE association, Goldenhar syndrome, frontonasal dysplasia, Meckel-Gruber syndrome, velocardiofacial syndrome, Genoa syndrome, Lambotte syndrome, Martin syndrome, and Steinfeld syndrome, as well as several teratogenic syndromes such as diabetic embryopathy, accutane embryopathy, and fetal alcohol syndrome. Holoprosencephaly has been linked to at least 12 different loci on 11 different chromosomes. Some candidate genes are Sonic hedgehog (abbreviated *SHH* and located at 7q36), *SIX3* (located at 2p21), and *ZIC2* (located on chromosome 13). The gene causing Smith-Lemli-Opitz syndrome, which affects cholesterol synthesis, is also a candidate to cause holoprosencephaly.

SHH, cholesterol, the prechordal plate, and the cause of holoprosencephaly

Holoprosencephaly probably arises in one of two ways (suggested by experiments in animal models). Early in the life of an embryo, an area called the prechordal plate forms. The prechordal plate is an area of the embryo that is

important for the formation of the brain. The prechordal plate is said to induce brain formation. One can think of the induction process in the following way. If you take a sponge, wet it, and then place a paper towel on top of it, the paper towel will absorb some of the water. In the same way, a signal (the water) goes from the sponge (prechordal plate) to the paper towel (future brain tissue). If the water does not hit the paper towel, brain tissue will not form. This is an extremely simplified version of how the process works, for many reasons. One is that the prechordal plate is not the only “sponge.” The notochord is another sponge, which sends out the signal (water) of *SHH* to form brain and spinal cord and other nervous tissue. Of course, *SHH* has already been mentioned as a candidate for a gene that causes holoprosencephaly. As it turns out, it is better than a candidate, because mutations in *SHH* have been found in some familial forms of holoprosencephaly. Further evidence that *SHH* plays a role in holoprosencephaly comes from *SHH* in mice and fish, which both result in holoprosencephaly. Thus, it would be a clear-cut picture if mutations in *SHH* and *SHH* alone led to holoprosencephaly, because *SHH* mutations lead to holoprosencephaly in other animals and *SHH* is already known to be involved in the formation of neural tissue.

However, *SHH* is not the only answer. Many persons with holoprosencephaly have perfectly normal *SHH* genes, and, as previously mentioned, a number of genes have been linked to holoprosencephaly, including genes involved in cholesterol synthesis. So why are so many genes involved?

One possible answer stems from the connection between cholesterol and the *SHH* signaling pathway. When *SHH* travels from one tissue to another tissue, there are a number of other genes involved before *SHH* has its final effect. This process is called signal transduction, and the genes that make it up are part of a signaling pathway. Signal transduction can be compared to a shot in the game of pool. When shooting pool, one must take the cue (*SHH*) and hit the cue ball (another gene; for *SHH* this would be the gene *Patched*). The cue ball goes on to hit the ball that one is interested in sinking (in this case, sinking the ball means making a normal brain). Thus, each step depends on the previous step and the next step. If one does not have the stick or the cue ball, one cannot sink the ball in the pocket. Thus, a number of mutations in genes in the *SHH* signaling pathway, and not just *SHH*, could cause holoprosencephaly. Other genes involved in cholesterol biosynthesis can have effects on genes in the *SHH* signaling pathway. Cholesterol appears to affect the function of the gene *Patched*. In the pool example, a lack of cholesterol would not mean the cue ball is gone, but maybe that the cue ball has a big lump on one side, so the shot is likely to miss.

KEY TERMS

Corpus callosum—A thick bundle of nerve fibers deep in the center of the forebrain that provides communications between the right and left cerebral hemispheres.

Craniofacial—Relating to or involving both the head and the face.

Induction—Process where one tissue (the prechordal plate, for example) changes another tissue (for example, changes tissue into neural tissue).

Neural—Regarding any tissue with nerves, including the brain, the spinal cord, and other nerves.

Another possible answer comes from studies on bone morphogenetic proteins (BMPs) in chickens. The presence of too much BMP in a chick embryo after the time neural tissue is formed can cause holoprosencephaly. It appears that there are two stages that can be interfered with—one that occurs at the time of neural tissue formation involving *SHH* and another that occurs later, involving BMPs. Increased levels of BMPs may cause important neural cells to die. It has been speculated that holoprosencephaly is either a failure to grow neural cells due to failure in the *SHH* pathway, or an excess of neural cells dying, possibly as a result of increased levels of BMPs. Both may end up being true, with some *SHH* signaling defects early and BMP mutations later.

Teratogens also cause holoprosencephaly

A teratogen is any environmental influence that adversely affects the normal development of the fetus. Teratogens can be skin creams, drugs, or alcohol. Alcohol, when ingested in sufficient amounts during the second week of pregnancy, is thought to lead to some cases of holoprosencephaly. Cytomegalovirus infections in the mother during pregnancy have been associated with holoprosencephaly. Additionally, in animals, drugs inhibiting cholesterol synthesis have been shown to cause cases of holoprosencephaly. Finally, the drug cyclopamine, which affects the *SHH* pathway, also causes holoprosencephaly in animals. Cyclopamine was discovered when an abnormally large number of sheep were found to have holoprosencephaly. A local shepherd and scientists determined the drug was found in a fungus called *Veratrum californicum*.

Demographics

Holoprosencephaly affects males and females at the same rate. Estimates vary on the frequency of the disorder

in children with normal chromosomes. The estimates range from one case in every 11,363 births to one case in 53,394 births. It is important to note that this rate of incidence excludes those cases caused by chromosomal abnormalities, like trisomy 13.

Signs and symptoms

In holoprosencephaly alone, symptoms involve the brain and/or the face and bones of the face and skull. Facial abnormalities exhibit a wide range. In the most severe cases, persons with holoprosencephaly lack eyes and may lack a nose. Less severe is cyclopia, or the presence of a single eye in the middle of the face above the possibly deformed or absent nose. Even less severe are ethmocephaly and cebocephaly, in which the eyes are set close together and the nose is abnormal. In premaxillary agenesis, the patient has a midline cleft lip and cleft palate and close-set eyes. If the face is very abnormal, the patient is likely to have alobar holoprosencephaly, the most severe type. In addition to abnormalities of the face, children with alobar holoprosencephaly have small brains (less than 100 grams). These children also have small heads unless they have excess cerebrospinal fluid. Excess cerebrospinal fluid can cause the head to be abnormally large.

Persons with holoprosencephaly experience many problems due to brain malformations, including *in utero* or neonatal death. Survivors may experience seizures, problems with muscle control and muscle tone, a delay in growth, problems feeding (choking and gagging or slowness, pauses, and a lack of interest), intestinal gas, constipation, hormone deficiencies from the pituitary, breathing irregularities, and heart rhythm and heart rate abnormalities. These problems are usually least severe in lobar holoprosencephaly and most severe in alobar. Children with holoprosencephaly also experience severe deficiencies in their ability to speak and in their motor skills. An ominous sign that children with holoprosencephaly may exhibit is a sustained (lasting many hours or days) period of irregular breathing and heart rate. This may precede death. Episodes lasting only minutes are usually followed by a full recovery.

Diagnosis

Prenatal ultrasound and computerized tomography can be used to determine whether the fetus has holoprosencephaly and its severity. After birth, physical appearance and/or imaging of the brain can determine a diagnosis of holoprosencephaly. Once a diagnosis of holoprosencephaly has been made, syndromes of which holoprosencephaly is a part must be considered. Forty-one percent of holoprosencephaly cases are thought to

have a chromosomal abnormality as the primary cause. Holoprosencephaly is estimated to be found in the context of a larger syndrome in 25% of the remaining patients.

Treatment and management

Although no treatment exists for the underlying disease, symptomatic treatment can reduce the amount of fluid surrounding the brain and assist in feeding. Medical intervention can reduce or eliminate seizures and hormonal deficiencies. However, few treatments exist for the most serious aspects of the disease—breathing and heart arrhythmias (irregular heart rate)—or for the problems associated with developmental delay and poor muscle control. One important aspect of treatment is to help parents understand the effects of the disease and what may be expected from the child. Support groups may be important for this purpose. Parents should be prepared to deal with a large number of healthcare professionals based on their child's particular needs.

Prognosis

About half of the children born with alobar holoprosencephaly die before the age of four to five months, but a much longer survival time is possible, up to at least 11 years. Children with semilobar and lobar holoprosencephaly may live for any length of time. Depending on the severity of the holoprosencephaly, however, parents should be prepared for differences in their child. For example, children with alobar holoprosencephaly and semilobar holoprosencephaly learn to speak very little, if at all, and children with alobar holoprosencephaly have difficulty even mastering the simple task of reaching and grasping an object. On the other end of the spectrum, children may develop much more normally. It is very important to understand the severity of the disorder to understand the child's abilities and possibilities.

Holt-Oram syndrome

Definition

Holt-Oram syndrome (HOS) is one of several hereditary conditions characterized by abnormalities of the heart and hands at birth.

Description

HOS involves variable abnormalities of the heart and the hands or the hands and the arms. The heart abnormalities may range from disturbances in the electrical conduction pattern of the heart to severe structural defects requiring surgical intervention for survival. The abnormalities of the upper limbs are usually bilateral (occurring on both sides) and asymmetric (not identical from side to side). The severity of the upper limb changes may range from minor signs, such as clinodactyly (inward curvature of the fingers), to disabling defects, such as small or missing bones resulting in very short arms.

Some individuals with HOS are so mildly affected, they do not require any special care or treatment. Other individuals are severely affected and may have significant disability resulting from abnormalities of the arms or may have limited lifespans due to serious heart abnormalities. The signs of HOS are usually limited to the heart and skeleton. HOS does not cause intellectual disability.

Some references may use the alternative name of hand-heart syndrome. However, Holt-Oram syndrome is one of many hereditary hand-heart syndromes, so the two names are not truly interchangeable.

Genetic profile

HOS is inherited as an autosomal dominant condition, with variable expressivity (meaning that different individuals with HOS may have very different signs of the condition) and complete penetrance (meaning that every individual that has the genetic change causing the condition has some physical symptoms). An autosomal dominant condition requires the presence of only one

abnormal gene on a non-sex-linked chromosome for the disorder to occur. Some researchers have observed families with incomplete penetrance (meaning that not every individual with the gene abnormality shows symptoms) as well.

In some individuals and families, HOS is caused by mutations in the *TBX5* gene located on the long arm of chromosome 12. The *TBX5* gene encodes a transcription factor that helps regulate DNA expression. Other families with HOS do not show mutations in the *TBX5* gene, indicating that mutations in other genes can also cause HOS. HOS families that have *TBX5* mutations do not appear to differ significantly from those that do not.

Some patients with HOS have inherited it from an affected parent, whereas others have it as the result of a new change in a gene. The proportion of patients with HOS resulting from new mutations ranges from 8% to 85%. Regardless of where the gene came from, an affected individual has a 50% chance of passing on the gene and the condition to each child. It is difficult to pre-determine the severity of symptoms a child may have.

Demographics

Since HOS was first described in 1960, more than 200 cases have been reported in individuals of diverse ethnicity. The incidence of the condition has been estimated as 1 in 100,000 live births.

Signs and symptoms

All individuals with HOS have some degree of upper limb abnormality, and most (approximately 95% in familial cases) have defects or dysfunction of the heart. Other body parts and systems are usually not significantly affected by HOS.

Defects of the upper limbs

The limb abnormalities in HOS primarily affect the radial side (the inner or thumb side of the arm/hand). Involvement of the ulnar side (the outer side of the arm/hand, opposite the thumb) may also occur to a lesser degree. In some individuals, the abnormality of the upper limb may be very mild, such as hypoplasia (underdevelopment) of the muscle at the base of the thumb; limited rotation of the arm; or narrow, sloping shoulders. Rarely, severe abnormalities of the upper limbs may be present, resulting in extremely short, “flipper-like” arms. Abnormalities of the upper limb are always bilateral and usually asymmetric. In 90% of patients, the left side is more severely affected.

The thumb is the most commonly affected part of the upper limb in HOS and is affected in some way in 84% of

patients. Some individuals have three phalanges (or bones) in the thumb, resulting in a thumb that can bend in three places, like a finger. In other cases, the thumb may be hypoplastic (underdeveloped). Syndactyly (or skin webbing) may occur between the thumb and index finger.

Abnormalities of the fingers may include hypoplasia, underdevelopment, or absence of one or more fingers. Clinodactyly (inward curvature) of the fifth or “pinky” finger is also common. In some patients, polydactyly (extra fingers) has been reported.

The bones of the arms may also be affected by HOS. The radius (the inner bone of the forearm, adjacent to the thumb) may be hypoplastic or even missing. Such patients may have a lesser degree of hypoplasia of the ulna (outer bone of the forearm, opposite the thumb). The upper arm may be short. In rare cases, the bones of the arm are dramatically shortened, resulting in a tiny arm.

Individuals with HOS often appear to have narrow, sloping shoulders. This likely results from some degree of hypoplasia of the clavicles (collarbones), as well as decreased musculature that occurs secondarily to bone hypoplasia.

Defects and dysfunction of the heart

The vast majority (95%) of individuals with HOS who have inherited it from an affected parent have heart involvement. Most have a defect in the structure of the heart. In some patients, there is no structural defect in the heart, but abnormalities are present in the pattern of electrical conduction in the heart.

The most common heart abnormalities in people with HOS are septal defects, or holes in the heart. A hole may occur in the wall separating the atria of the heart (atrioseptal defect or ASD) or the wall separating the ventricles of the heart (ventriculoseptal defect or VSD). In rare cases, more severe and complex heart defects may occur, such as hypoplastic left heart (in which the chambers of the left side of the heart are too small to function normally) or tetralogy of fallot (a specific combination of four heart defects). In the case of severe defects, surgical correction is necessary for survival. However, most persons with HOS do not require surgical intervention.

Some individuals with HOS have a cardiac conduction defect, or an abnormal electrical pattern in the heart. The complex motion of the heart requires a system of electrical impulses for coordinated contraction of the muscle fibers. In people with cardiac conduction defects, these electrical impulses may not occur in the normal pattern, resulting in an abnormal heartbeat. In rare cases, this can result in sudden death.

KEY TERMS

Atria—The two chambers at the top of the heart, where blood from the lungs or body pools before entering one of the ventricles.

Polydactyly—The presence of extra fingers or toes.

Radius—One of the two bones of the forearm, the one adjacent to the base of the thumb.

Septal defect—A hole in the heart.

Syndactyly—Abnormal webbing of the skin between the fingers or toes.

Ulna—One of the two bones of the forearm, the one opposite the thumb.

Ventricles—The chambers (small cavities) of the heart through which blood circulates. The heart is divided into the right and left ventricle.

Other defects

Additional skeletal abnormalities occasionally reported in patients with HOS include scoliosis, vertebral abnormalities, and minor deformities of the rib cage. Some patients may have abnormalities unrelated to the cardiac or skeletal systems, such as minor eye defects and various birthmarks. It is not clear whether these additional findings are coincidental or part of HOS.

Diagnosis

The diagnosis of HOS is made on the basis of clinical judgment by a specialist physician, usually a geneticist, following physical examination and review of pertinent tests or studies. Diagnostic criteria may be employed to guide this decision. One commonly used set of criteria for the diagnosis of HOS requires that there be defect(s) of the radial side of the hand/arm, as well as septal defect(s) or conduction abnormality of the heart, within one individual or family.

X-rays may be necessary to determine involvement of the bones of the upper limb. Diagnosis of structural defects of the heart requires echocardiography, or ultrasound visualization of the heart. Conduction defects of the heart are identified via electrocardiography (EKG). This test involves measuring the electrical activity of the heart and charting the electrical impulses associated with each heartbeat.

Testing to identify changes in the *TBX5* gene may be offered but is not necessary for a diagnosis of HOS. Identification of a change or alteration in the *TBX5* gene could provide confirmation of the clinical diagnosis, prenatal

diagnosis, or assist in the diagnosis of at-risk family members who are minimally affected. Prenatal screening in a pregnancy at risk for HOS may be attempted by fetal ultrasonography targeted toward the fetal arms and heart. However, a normal ultrasound examination does not eliminate the possibility of HOS in the unborn baby.

Treatment and management

There is no specific treatment for HOS. Surgery or other treatment may be recommended for cardiac abnormalities. Referral for genetic counseling should be considered for families in which HOS has been diagnosed.

Some patients with HOS have life-threatening heart defects that require surgical correction for survival. The most complex heart defects may require multiple surgeries. However, many individuals have asymptomatic or no heart abnormalities. When life-threatening irregularities are present in the heartbeat, a pacemaker device is inserted. These devices correct the abnormal electrical patterns that cause the irregularities and stimulate the heart to beat normally.

Because eye abnormalities have been occasionally reported in HOS, an eye examination may be recommended at the time of diagnosis.

Prognosis

The prognosis for individuals with HOS depends on the severity of associated birth defects, which varies considerably. Positive correlation has been reported between the severity of upper limb and heart defects. In other words, individuals who have more severe hand or arm involvement may be more likely to have a symptomatic heart defect. People who have HOS resulting from new mutations are more likely to have severe defects than those who have inherited it from a parent.

In some cases, HOS may lead to death in early infancy due to multiple septal defects or other complex structural abnormalities of the heart. Severe and unrecognized disturbances of the cardiac conduction system can lead to sudden death. In other cases, heart involvement is limited to asymptomatic irregular heartbeat requiring no treatment.

Several unusual findings have been described with respect to the severity of HOS in families. Affected women have been reported to have a higher chance of having a severely affected child than do affected men. The severity of defects associated with HOS has also been reported to increase with successive generations. The possible explanations for these observations are not known.

QUESTIONS TO ASK YOUR DOCTOR

- What are the most common symptoms associated with Holt-Oram syndrome?
- Is there a genetic test that I can take to see if my children will be at risk for Holt-Oram syndrome?
- How is it possible to predict the course of Holt-Oram syndrome in a child who is diagnosed with the disorder as an infant?
- Are there other medical conditions with which a diagnosis of Holt-Oram syndrome might be confused and, if so, how is it possible to distinguish among these conditions?

Homocystinuria

Definition

The term "homocystinuria" is actually a description of a biochemical abnormality, as opposed to the name of a particular disease, although many refer to

homocystinuria as a disease. Homocystinuria refers to elevated levels of homocysteine in the urine. This can be caused by different biochemical abnormalities, and, in fact, there are at least eight different gene changes that are known to cause excretion of too much homocysteine in the urine. The best known and most common cause of homocystinuria is the lack of cystathionine β -synthase. Classical homocystinuria is caused by cystathionine β -synthase deficiency (CBS deficiency).

Description

In Northern Ireland in the early 1960s, homocystinuria was described in individuals who were intellectually disabled. Soon after that, it was shown that the cause of the homocystinuria was a deficiency of the enzyme cystathionine β -synthase. This condition is an inborn error of metabolism, meaning that the cause for this condition is present from birth and it affects metabolism.

Metabolism is the sum of all of the chemical processes that take place in the body. Metabolism includes both construction (anabolism) and breakdown (catabolism) of important components. For example, amino acids are the building blocks for proteins and are converted to proteins through many steps in the process of anabolism. In contrast, proteins can also be broken down into amino acids through many steps in the process of catabolism. These processes require multiple steps that involve different substances called enzymes. These enzymes are proteins that temporarily combine with reactants and, in the process, allow these chemical processes to occur quickly. Since practically all of the reactions in the body use enzymes, they are essential for life. At any point along the way, if an enzyme is missing, the particular process that requires that enzyme would not be able to be completed as usual. Such a situation can lead to disease.

Homocysteine is involved with the catabolism of methionine. Methionine is an essential amino acid. Amino acids are the building blocks of proteins. Over 100 amino acids are found in nature, but only 22 are found in humans. Of these 22 amino acids, eight are essential for human life, including methionine. Methionine comes from dietary protein. Generally, the amount of methionine that is consumed is more than the body needs. Excess methionine is converted to homocysteine, which is then metabolized into cystathionine; cystathionine is then converted to cysteine. The cysteine is excreted in the urine. Each step along this pathway is carried out by a specific enzyme and that enzyme may even require help from vitamin co-factors to be able to complete the job. For example, the conversion of homocysteine to cystathionine by cystathionine β -synthase requires vitamin B₆ (pyridoxine). If cystathionine β -synthase is

Flow chart for the chemical processes involved in the breakdown of methionine, an essential amino acid found in dietary protein. Homocystinuria results when the enzyme cystathionine β -synthase is missing and does not break down homocysteine, a converted form of excess methionine. The elevated levels of methionine and homocysteine that result from the failure of homocysteine to break down into cystathionine and cysteine causes a disease state that affects multiple body systems. (Gale)

missing, then homocysteine cannot be broken down into cystathionine and cysteine and, instead, homocysteine accumulates and elevated levels of homocysteine and methionine can be found in the blood. Also, decreased levels of cysteine can be found in the blood. Elevated levels of homocysteine lead to a disease state that, if untreated, affects multiple systems, including the central nervous system, the eyes, the skeleton, and the vascular system.

Genetic profile

Classical homocystinuria or cystathionine β -synthase (CBS) deficiency is an autosomal recessive condition. This means that in order to have the condition, an individual must inherit one copy of the gene for CBS deficiency from each parent. An individual who has only one copy of the gene is called a carrier for the condition. In most cases of autosomal recessive inheritance, a carrier for a condition does not have any signs, symptoms, or effects of the condition. This is not necessarily the case with CBS deficiency. Individuals who are carriers for CBS deficiency may have levels of homocysteine that are elevated enough to increase the risk for thromboembolic

events. So, although carriers may not exhibit obvious physical signs or symptoms of the condition, they may have clinical effects of elevated levels of homocysteine, such as vascular or cardiovascular disease. A carrier for CBS deficiency can have vascular complications, especially if they are also carriers for other clotting disorders such as factor V Leiden thrombophilia.

When two parents are carriers for CBS deficiency, there is a 1 in 4 (or 25%) chance, with each pregnancy, for having a child with CBS deficiency. They have a 1 in 2 (or 50%) chance for having a child who is a carrier for the condition, and a 1 in 4 (or 25%) chance for having a child who is neither affected nor a carrier for CBS deficiency.

The gene for CBS has been mapped to the long arm of chromosome 21, specifically at 21q22.3. Approximately 160 different disease-associated gene changes or alterations of the CBS gene have been identified. The two most frequently encountered gene changes are *I278T* and *G307S*. *G307S* is the most common cause of CBS deficiency in Irish patients, and the *I278T* gene is the most common cause of CBS deficiency in Italian patients.

Homocystinuria: pedigree analysis chart. (Gale)

Demographics

The worldwide frequency of individuals with CBS deficiency who are identified through newborn screening and clinical detection is approximately 1 in 344,000; however, newborn screening may be missing half of affected patients, and thus, the worldwide incidence may be as high as 1 in 180,000. One study showed that by lowering the cutoff level of methionine from 2 milligrams per deciliter to 1 milligram per deciliter in newborn screening, detection of the deficiency increased from 1 in 275,000 to 1 in 157,000. The incidence of CBS deficiency in the U.S. population is 1 in 58,000. In the Irish population, it is estimated to be 1 in 65,000; in the Italian population it is 1 in 55,000; and in the Japanese population, it is 1 in 889,000. CBS deficiency has been seen in persons of many different ethnic origins living in the United States.

Signs and symptoms

Individuals who have CBS deficiency tend to be tall and thin with thinning and lengthening of the bones. They tend to have a long, narrow face and a high, arched palate (roof of the mouth). The thinning and lengthening of the long bones causes individuals to be tall and thin by the time they reach late childhood. Their fingers tend to be long and thin as well (referred to as arachnodactyly). They can have curvature of the spine, called scoliosis. Their chest can be sunken in (pectus excavatum), or it may protrude out (pectus carinatum). Osteoporosis may occur. Also, they tend to have stiff joints. CBS deficiency affects the eyes, causing dislocated lenses and nearsightedness (myopia). Untreated individuals or those individuals who do not respond to treatment develop intellectual disabilities or learning disabilities. Affected individuals may also develop psychiatric problems. These psychiatric problems may include depression,

chronic behavior problems, chronic obsessive-compulsive disorder, and personality disorders. The most frequent cause of death associated with CBS deficiency is blood clots that form in veins and arteries. These are known as thromboembolisms and include deep vein thrombosis (blood clots that form in the deep veins of the legs, etc.), pulmonary embolus (blood clots that form in the lungs), and strokes. Thromboembolism can occur even in childhood. When thromboembolism does occur in childhood, CBS deficiency should always be considered as a cause for the thromboembolic events. These thromboembolic events can occur in any part of the body. Lastly, another complication of CBS deficiency is severe premature arteriosclerosis (hardening of the arteries).

Diagnosis

Approximately 50% of individuals who have CBS deficiency are diagnosed by newborn screening because they have an elevated level of methionine in their blood. Newborn screening is performed so that infants affected with genetic disorders can be identified early enough to be treated. The screening is done by collecting blood from a pin-prick on the baby's heel prior to leaving the hospital but at least 24 hours after birth. For CBS deficiency, the screening test checks for elevated levels of methionine. If the levels are elevated, then follow-up testing to verify the diagnosis is performed. There are other disorders of methionine metabolism, and follow-up testing determines the underlying cause of the positive newborn screening.

If not identified at newborn screening, diagnosis is made by identifying low levels of cysteine in blood and urine. Measurements of the amount of methionine and homocysteine produced by cultured blood cells (lymphoblasts) or cultured skin cells (fibroblasts) also can confirm the diagnosis of CBS deficiency.

DNA testing is available for families in which a gene alteration is identified. Potentially, this makes prenatal diagnosis by chorionic villus sampling (CVS) and amniocentesis available for families who have had a previously affected child and in which two identifiable gene alterations for CBS deficiency have been detected. Prenatal diagnosis is also possible by measuring the amount of enzyme activity in cultured cells grown from amniotic fluid.

CBS deficiency has several features in common with Marfan syndrome, including the tall, thin build with long limbs and long, thin fingers (arachnodactyly); a sunken-in chest (pectus excavatum); and dislocated lenses. The dislocated lens in Marfan syndrome tends to be dislocated upward; the tendency for the lens dislocation is to be downward in CBS deficiency. Also, individuals who have Marfan syndrome tend to have lens dislocation from birth (congenital), whereas individuals who have CBS deficiency have not been identified to have lens dislocation before two years of age.

Treatment and management

The first choice of therapy for patients with CBS deficiency is administration of pyridoxine (vitamin B₆). Vitamin B₆ is the cofactor for the cystathionine β -synthase reaction. Potentially, some individuals who have CBS deficiency are not missing the enzyme, but rather have an enzyme that is unable to perform its job. The addition of pyridoxine can help to push the reaction along and help to reduce the levels of homocysteine and methionine in the blood. Information suggests that approximately 50% of patients with CBS deficiency respond to high doses of pyridoxine (pyridoxine responsive) and show a significant reduction in levels of homocysteine in the blood. Patients who do not respond to pyridoxine treatment (pyridoxine non responsive) tend to be more severely affected than the patients who do respond. Those nonresponding patients are treated with combinations of folic acid, hydroxycobalamin, and betaine, which stimulate the conversion of homocysteine back to methionine. The addition of folic acid can help because within the methylene H₄-folate molecule (MTHFR), there is a molecule known as flavin adenine dinucleotide (FAD). The FAD molecule binds to the MTHFR molecule and helps with the conversion of homocysteine to methionine. Increased levels of folate help bind FAD more tightly to MTHFR, protecting the enzyme against heat inactivation and allowing the homocysteine-to-methionine-conversion pathway to proceed. Betaine and cobalamin also help in the conversion of homocysteine to methionine by acting as cofactors. The rationale behind this method of treatment is that although the methionine levels are raised, the net

drop in homocysteine is beneficial, as it appears that the elevated levels of homocysteine are what cause ectopia lentis, osteoporosis, mental deficiency, and thromboembolic events.

It appears that the addition of dietary betaine in B₆-responsive patients is also beneficial. Homocysteine that is not metabolized to cysteine is converted back to methionine in a reaction that uses betaine, so the addition of betaine may help to make this reaction occur and thus reduce the levels of homocysteine.

Other treatments include protein restriction, specifically a low-methionine diet with the addition of extra cysteine. Dietary treatment includes avoidance of all high-protein foods throughout life, with the use of a nutritional supplement. Special formulas for infants are available. The reasoning behind this is to reduce the methionine and homocysteine levels that accumulate and supplement the low levels of cysteine.

The occurrence of clinically apparent thromboembolism depends upon the age of the affected individual and whether or not he/she responds to pyridoxine treatment. In one study, untreated pyridoxine-responsive patients were at little risk for a thromboembolic event until age 12. After age 12, the risk for thromboembolism increased. By age 20, patients who would have been responsive to pyridoxine had a 25% cumulative risk for a thromboembolic event. In comparison, individuals with CBS deficiency who were untreated and not responsive to pyridoxine treatment had a similar cumulative risk for a thromboembolic event by age 15.

In reference to the two common CBS gene alterations, CBS deficiency caused by the *I278T* gene change is pyridoxine responsive. CBS deficiency caused by the *G307S* gene tends to be pyridoxine nonresponsive; however, this is not always the case, as some individuals with the *G307S* gene change are pyridoxine responsive.

Very little is known about the risks to an unborn child of a mother with pyridoxine nonresponsive CBS deficiency. There have been numerous reports of healthy children born to women and men who have pyridoxine-responsive CBS deficiency; however, only two reports of children born to pyridoxine nonresponsive women have been reported, and one had multiple birth defects that may have been related to the mother's condition. Potentially, the mother's elevated levels of homocysteine can cause problems for a developing baby. This could be similar to the process by which infants of mothers who have phenylketonuria are affected by the elevated levels of phenylalanine if their mothers are not being treated with dietary restriction during pregnancy.

KEY TERMS

Anabolism—The energy-using process of building up complex chemical compounds from simpler ones in the body.

Catabolism—The energy-releasing process of breaking down complex chemical compounds into simpler ones in the body.

Marfan syndrome—A syndrome characterized by skeletal changes (arachnodactyly, long limbs, lax joints), ectopia lentis, and vascular defects.

Thrombophilia—A disorder in which there is a greater tendency for thrombosis (clot in blood vessel).

Prognosis

Untreated CBS deficiency leads to intellectual disability, lens dislocation, and a decreased life expectancy because of complications associated with blood clots. If untreated from early infancy, approximately 20% of affected patients will have seizures. If treated from birth, prevention or long-term delay of the complications of CBS deficiency can be expected.

Human Genome Project

Definition

The Human Genome Project (HGP) was an international project to sequence the DNA of the human genome. The sequencing work was conducted in many laboratories around the world, but the majority of the work was done by five institutions: the Whitehead Institute for Medical Research (WIMR) in Massachusetts, the Baylor College of Medicine in Texas, the Washington University, the Joint Genome Institute in California, and the Sanger Centre near Cambridge in the United Kingdom. Most of the funding for these centers was provided by the U.S. National Institutes of Health and Department of Energy, and the Wellcome Trust, a charitable foundation in the United Kingdom.

Description

Completely sequencing the human genome was first suggested at a conference in Alta, Utah, in 1984. The conference was convened by the U.S. Department of Energy, which was concerned with measuring the mutation rate of human DNA when exposed to low-level radiation, similar to conditions after an attack by nuclear weapons. The technology to make such measurements did not exist at the time, and the sequence of the genome was one step required for this aim to become possible. The genome was estimated to be 3,000Mb long, however, and sequencing it seemed an arduous task, especially using the sequencing technology of the time. If most of the DNA was "junk" (not coding for genes), scientists assumed that they could speed the process along by targeting specific genes for sequencing. This could be done by sequencing complementary DNA (cDNA), which are derived from mRNA used to code for proteins in the cell. Despite several advocates for this method, it was decided that the whole genome would be sequenced, with a 2005 target completion date. Goals for the HGP included identifying all of the approximately 20,000–25,000 genes in human DNA; determining the sequence of the three billion base pairs that make up human DNA; storing this information in retrievable databases; and addressing the ethical, legal, and social issues that would inevitably arise from the project. The HGP quickly became the world's premier science project for biology, involving large factory-like laboratories rather than small laboratories of independent geneticists.

The strategy employed by the HGP involved three stages and is termed hierarchical shotgun sequencing. The first stage involved generating physical and genetic

maps of the human genome. The second stage was placing clones from a genomic library onto these maps. The third stage was fragmenting these genomic clones into smaller overlapping clones (shotgun cloning), which were a more suitable size for sequencing. Then, the complete sequence of each chromosome could be reconstructed by assembling the fragments of sequence that overlapped with each other to generate the sequence of the genomic clone. The sequence of each genomic clone could then be fitted together using the assembly (contig) of genomic clones on the genetic and physical map.

Although the ultimate aim was a high-quality sequence of the human genome, it was recognized that the genetic and physical maps generated by the first stage of the HGP would be by themselves very useful for genetic research. The first-generation physical map was constructed by screening a yeast artificial chromosome (YAC) genomic library to isolate YACs, and overlaps were identified by restriction enzyme digest “fingerprints” and STS content mapping. These STSs were sequenced around the highly polymorphic CA-repeat markers (microsatellites) that were used to generate the genetic map. Genetic maps were also constructed. These use recombination between markers in families to deduce the distance separating and order of these markers. The first human genetic map used restriction fragment-length polymorphisms (RFLPs) as markers, which have only two alleles per marker, but common microsatellites were used to create a high-resolution genetic map.

The second stage of human genome sequencing was made simpler by the development of bacterial artificial chromosomes (BACs), cloning vectors that could carry up to 150kb of DNA. Before then, it was assumed that a contig of YACs and cosmids, carrying up to 2Mb and 40kb of DNA, respectively, would be assembled. These two types of genomic clones were found to be liable to rearrangement; the DNA in the vector could be in chunks that were not necessarily in the same order as in the genome. The BAC vector did not rearrange DNA and could carry more DNA than many other types of genomic clone.

The third stage was made easier by development of high-throughput DNA sequencing and affordable computing power to enable reassembly of the sequence fragments. It was these developments that led to the idea of whole-genome shotgun sequencing of the human genome. In contrast to the HGP plan involving the use of genetic contigs and physical maps as a framework for genomic clones and sequence, scientists suggested that the whole genome could be fragmented into small chunks for sequencing and then reassembled using overlap

between fragment sequences (whole-genome shotgun sequencing). This required large amounts of computing power to generate the correct assembly but was considerably faster than the HGP approach. Many scientists did not believe that this method would assemble the genome properly and suggested that overlap between small fragments could not be the only guide to assembly, because the genome contained many repeated DNA sequences. American biochemist J. Craig Venter believed the method could work and formed Celera, a private company that would sequence the human genome before the HGP.

Celera demonstrated that the whole-genome shotgun method would work by sequencing the genome of a model organism, the fruit fly *Drosophila melanogaster*. Despite the successful sequencing of the fly, many people were still skeptical that the method would be successful for the bigger human genome. The publicly funded HGP, in light of Celera’s competition, decided to concentrate, like Celera, on a draft of the human genome sequence (3× coverage—that is, each nucleotide has been sequenced an average of three times) before generating a more accurate map of 8× coverage. Celera had an advantage because the HGP had agreed to release all its data as it was generated onto a freely accessible database, as part of the Bermuda rules (named after the location of a series of meetings during the early stages of the HGP). This allowed Celera to use HGP data to link its sequence fragments with the BAC contigs and genetic/physical maps.

The human genome draft sequence of both groups were published in February 2001 by Celera and the HGP consortium in the journals *Science* and *Nature*, respectively. Celera had imposed restrictions on access to its genomic data, and this was a source of disagreement between the private company and the HGP. Celera scientists argue that their methods are cheaper and quicker than the HGP framework method, but HGP scientists, in turn, argue that Celera’s assembly would not have been possible without the HGP data. No matter who eventually takes credit, the finalized complete sequence was completed in 2003.

For human geneticists in general, and medical researchers in particular, the genome sequence is abundantly useful. The ability to identify genes, single-nucleotide polymorphisms, from a database search speeds up research. Previously, mapping and finding (positional cloning) a gene would take several years of research, a task that now takes several minutes. The investment in the sequencing centers continue to be of use, with a mouse sequencing project underway and many genomes of pathogenic bacteria sequenced.

This study of genomes and parts of genomes has been called genomics. The medical benefits of genomics were emphasized throughout the project, partly to ensure continuing government support. These benefits are not likely to be immediate or direct, but the genome sequence will have a significant effect on pharmacogenomics, which studies how genetic variants affect how well a drug can treat a disease. In addition, through pharmacogenomics it is hoped that there will be a substantial increase in the design of more effective drugs with lower toxicity by tailoring drug treatment to a patient's individual genetically determined drug metabolism.

The HGP has also given scientists more powerful tools in elucidating the determinants of cancer susceptibility. In many ways, cancer can be considered as a complex genetic trait, where the interaction between a person's genes and environment interact in such a way to confer a variable degree of risk of developing cancer. Through information gained from the HGP, a significant amount of information has been gleaned about high-penetrance genes that are responsible for some familial aggregations of cancer, such as the BRCA mutations and their association with breast cancer.

The impact on nonscientists has been substantial, with the HGP suggested to be the ultimate in self-knowledge.

Huntington's disease

Definition

Huntington's disease (HD) is a progressive, neurodegenerative disease causing uncontrolled physical movements and mental and emotional deterioration, as well as personality changes. Many people with this diagnosis die early but not directly from the disease itself. Instead, many die from choking, injuries from falls, or infections such as pneumonia. The disease was first discovered in 1872 by George Huntington of Pomeroy, Ohio, who described this hereditary movement disorder. The gene causing Huntington's disease was discovered in 1993 by James Gusella and colleagues after ten years of exhaustive research. HD is rare, and according to experts P. McCloghan and S.J. Tabrizi, the prevalence is about 11 to 14 individuals for every 100,000 people.

Description

Huntington's disease is also called Huntington's chorea, from the Greek word for "dance," referring to the involuntary movements that develop as the disease progresses. It is occasionally referred to as "Woody Guthrie's disease" for the American folk singer who died from it. HD affects the basal ganglia and cerebral cortex, areas of the brain responsible for some aspects of movement control and mental functioning, causing a progressive loss of cells in those areas. A person with HD gradually develops abnormal movements and changes in cognition, behavior, and personality.

Demographics

The onset of symptoms usually occurs between the ages of 30 and 50, although in 10% of cases, the onset is in late childhood or early adolescence. In a study of subjects carrying the gene for Huntington's disease, Jordan L. Schultz, PharmD and colleagues compared "premanifest" participants (who did not yet have symptoms although they carried the gene for Huntington's disease) to those with symptoms, and they found a significant relationship between hypertension and an earlier diagnosis of Huntington's disease. In contrast, patients who had the HD gene but who had normal blood pressure had a significantly lower risk of receiving an early diagnosis of HD. Further research is needed, but if this study is validated, this may mean that keeping blood pressure to normal levels may delay the onset of symptoms in patients with the genetic mutation for Huntington's disease.

Genetic profile

Huntington's disease is caused by a change in the *HTT* gene located on chromosome 4 at 4p16.3. This gene

Molecular genesis of Huntington's disease. Expansion of the CAG trinucleotide sequence in the *htt* gene causes production of mutated Huntingtin protein leading to neurodegeneration, atrophy of brain basal ganglia, involuntary movements, and dementia. (Kateryna Kon/Science Source)

contains the coding for producing a protein called huntingtin (not a misspelling). While the full function of the huntingtin protein is not understood, researchers know that it is involved in the production and/or maintenance of neurons (nerve cells) in the brain. The gene for Huntington's disease is present at birth, but symptoms usually do not occur until middle age; however, rarely children may develop early symptoms, which is referred to as juvenile Huntington's disease. If the mutated gene is present, then symptoms will inevitably develop at some point.

The mutation in the *HTT* gene responsible for HD is found in the nucleotide coding region known as the CAG trinucleotide repeat. Normally, this section repeats 10 to 35 times; however, in individuals with HD, this section contains anywhere from 36 to over 120 repeats. The extra building blocks in the *HTT* gene cause the protein that is made from it to contain an extra section as well. It is currently thought that this extra protein section, or portion, interacts with other proteins in brain cells where it ultimately leads to cell death.

The *HTT* gene mutation is inherited in an autosomal dominant gene, meaning that only one copy of it is needed to in order develop the disease. HD affects both males and females. The mutation may be inherited from either parent, who will also be affected by the disease. A parent with the *HTT* gene mutation has a 50% chance of passing it on to each offspring. The chances of passing

on the *HTT* gene mutation are not affected by the results of previous pregnancies.

Signs and symptoms

The symptoms of HD fall into three categories: motor or movement symptoms, personality and behavioral changes, and cognitive decline. The severity and rate of progression of each type of symptom can vary from person to person.

Early motor symptoms include restlessness, twitching, and a desire to move about. Handwriting may become less controlled, and coordination may decline.

Later symptoms of HD include:

- Dystonia or sustained abnormal postures, including facial grimaces, a twisted neck, or an arched back.
- Chorea, in which involuntary jerking, twisting, or writhing motions become pronounced.
- Slowness of voluntary movements, inability to regulate the speed or force of movements, inability to initiate movement, and slowed reactions.
- Slurred speech and difficulty speaking and swallowing due to involvement of the throat muscles.
- Localized or generalized weakness and impaired balance ability.
- Rigidity, especially in late-stage disease.

Huntington's Disease: pedigree analysis chart. (Gale)

- Personality and behavioral changes, including depression, irritability, anxiety, and apathy. The person with HD may become impulsive, aggressive, or socially withdrawn.
- Cognitive changes, including loss of ability to plan and execute routine tasks, slowed thought, and impaired or inappropriate judgment.
- Short-term memory loss usually occurs, although long-term memory is usually not affected. The person with late-stage HD usually retains knowledge of his environment and recognizes family members or other loved ones, despite severe cognitive decline.

Diagnosis

Diagnosis of HD begins with a detailed medical history and a thorough physical and neurological exam. Family medical history is very important. Magnetic resonance imaging (MRI) or computed tomography (CT) scan imaging may be performed to look for degeneration in the basal ganglia and cortex, the brain regions most affected by HD.

A genetic test is available for confirmation of the clinical diagnosis. In this test, a small blood sample is taken, and DNA from it is analyzed to determine the CAG repeat number. A person with a repeat number of 30 or below will not develop HD. A person with a repeat number between 35 and 40 might not develop the disease within their normal lifespan. A person with a very high

number of repeats (70 or above) is likely to develop the juvenile-onset form. One important part of genetic testing is extensive genetic counseling.

Prenatal testing is available. A person who is at risk for HD (such as the adult child of an affected person) may obtain fetal testing without determining whether the adult carries the gene. This test, also called a linkage test, examines the pattern of DNA near the gene in both parent and fetus but does not analyze for the triple nucleotide repeat (CAG). If the DNA patterns do not match, the fetus can be assumed not to have inherited the HD gene, even if it is present in the parent. A pattern match indicates that the fetus probably has the same genetic makeup of the at-risk parent.

Treatment and management

There is no cure for HD or any treatment that can slow the rate of progression, although researchers are actively seeking new therapies and treatments. Treatment is aimed at reducing the disability caused by the motor impairments and treating behavioral and emotional symptoms.

Physical therapy is used to maintain strength and compensate for lost strength and balance. Stretching and range-of-motion exercises help to minimize contracture, or muscle shortening, a result of weakness and disuse. A physical therapist can advise on the use of mobility aids such as walkers or wheelchairs.

KEY TERMS

Basal ganglia—The region of the base of the brain that controls involuntary movement.

Cerebral cortex—The outer layer of the brain, also called the gray matter, that is responsible for thinking and functions related to language.

Chorea—An involuntary movement disorder characterized by short, jerky motions of the body.

Computed tomography (CT) scan—An imaging test that uses computers and x-rays to produce detailed images of the body.

Dystonia—An involuntary movement disorder in which muscle contractions cause parts of the body to twist.

Magnetic resonance imaging (MRI)—An imaging test that uses computers and magnetic fields to produce detailed images of the body.

Nucleotide—The building blocks of DNA and RNA.

Motor symptoms may be treated with drugs, although some studies suggest that antichorea treatment rarely improves function. Chorea (movements caused by abnormal muscle contractions) can be suppressed with drugs that deplete dopamine, an important brain chemical that regulates movement. As HD progresses, natural dopamine levels fall, leading to loss of chorea and an increase in rigidity and movement slowness. Treatment with L-dopa (which resupplies dopamine) may be useful. Frequent reassessment of the effectiveness and appropriateness of any drug therapy is necessary. Individuals with HD may also be treated with antipsychotic medications to decrease the chorea symptoms as well as to manage delusions, hallucinations, and violent behavior. Antidepressants may be used to treat depression.

Occupational therapy is used to design compensatory strategies for lost abilities in the activities of daily living, such as eating, dressing, and grooming. The occupational therapist advises on modifications to the home that improve safety, accessibility, and comfort.

Difficulty swallowing may be lessened by preparation of softer foods, blending food in an electric blender, and taking care to eat slowly and carefully. Use of a straw for all liquids can help. The potential for choking on food is a concern, especially late in the disease progression. Caregivers should learn the use of the Heimlich maneuver. In addition, passage of food into the airways increases the risk for pneumonia. A gastric feeding tube

QUESTIONS TO ASK YOUR DOCTOR

- What kinds of examinations and diagnostic tests will be performed to determine whether I have Huntington's?
- Can my baby be tested for Huntington's?
- What do these exams and tests involve?
- How should I prepare for these exams and tests?
- Will other members of my family be tested? Why or why not?

may be needed if swallowing becomes too difficult or dangerous.

Speech difficulties may be partially compensated by using picture boards or other augmentative communication devices. Loss of cognitive ability affects both speech production and understanding. A speech-language pathologist can work with the family to develop simplified and more directed communication strategies, including speaking slowly, using simple words, and repeating sentences exactly.

Early behavioral changes, including depression and anxiety, may respond to drug therapy. Maintaining a calm, familiar, and secure environment is useful as the disease progresses. Support groups for patients and caregivers form an important part of treatment.

Gene therapy to treat HD holds great promise, and there are clinical trials underway. For example, the experimental drug AMT-130 reduces the amount of the mutated huntingtin (*HTT*) gene, the toxic fragments of which cause the symptoms of HD. This trial began in 2019 and is designed to follow 26 subjects with HD for five years.

Prognosis

The person with Huntington's disease may be able to maintain a job for several years after diagnosis, despite the increase in disability. Loss of cognitive functions and increase in motor and behavioral symptoms eventually prevent the person with HD from continuing employment. Ultimately, severe motor symptoms prevent mobility. Death usually occurs 15 to 20 years after disease onset. Progressive weakness of respiratory and swallowing muscles leads to increased risk of respiratory infection and choking, the most common causes of death in persons with HD. Future research in this area is currently focusing on nerve cell transplantation.

Hutchinson-Gilford progeria syndrome

Definition

Hutchinson-Gilford progeria syndrome (HGPS), formerly known as progeria syndrome, is an extremely rare genetic disorder of unknown origin that manifests as premature aging in children. HGPS affects many parts of the body including the skin, bones, and arteries.

Description

Dr. Jonathan Hutchinson in 1886 and Dr. Hastings Gilford in 1904 first described this syndrome. The word "progeria" is from the Greek word "geras," which means "old age." HGPS is also known as progeria syndrome or Gilford syndrome.

Most patients with this genetic abnormality appear normal at birth. Signs and symptoms usually begin to develop within the first one to two years of life. Changes in skin and failure to thrive (failure to gain weight) are usually evident first, the exception being four reported cases of possible neonatal progeria. All four infants died before 20 months of age. Death in these cases appears to be related to intrauterine growth retardation and presentation of HGPS signs and symptoms at birth. The neonatal cases did not exhibit the development of arteriosclerosis (hardening of the arteries). Arteriosclerosis is the most serious complication of HGPS. Complications secondary to arteriosclerosis in childhood, adolescence, or adulthood are the leading cause of death.

Patients with HGPS develop many other signs and symptoms that present a classical appearance. The majority of patients with HGPS resemble each other. Common external findings include aging at an accelerated rate, alopecia (hair loss), prominent scalp veins, absence of fat under the skin (subcutaneous fat), scleroderma (thickening of the skin), a pinched nose, small face and jaw (micrognathia) relative to head size (bird face), delayed tooth formation, high pitched voice, and impaired or absence of sexual development. Patients are also known to experience stiffening of various joints, bone structure abnormalities, and the development of arteriosclerosis. Patients with HGPS experience average intelligence, and their cognitive abilities are usually not affected.

Genetic profile

The gene mutation responsible for HGPS is the *LMNA* gene located on the short arm of chromosome 1. The mutation is typically due to a point mutation of the coding of this gene. The *LMNA* gene codes for the protein lamin-A, which determines the shape of the nucleus of cells. The alteration in this protein, named progerin, helps derive the name of the syndrome. The shape of the nucleus is extremely important for the correct replication of cells; therefore, it is necessary for the proper growth, development, and repair of the cells of the human body. When this protein is not coded properly, as seen in HGPS, the body will not develop properly and will lead to premature death of the cell, resulting in the typical signs and symptoms of HGPS. HGPS is passed on in an autosomal dominant new mutation fashion. The disorder is transmitted to children by autosomal dominant

Photo of Ontlametse Phalatse of South Africa, shown here at age 12, was at the time the only known black female born with the extremely rare premature aging disease. Phalatse died at age 18 in 2017. (AP Images/Denis Farrell)

inheritance. This means that either affected parent (father or mother) has a 50% chance of having a child (regardless of gender) with the disorder. New mutation refers to the chance change in the structure of a gene, resulting in alterations in its function. This new mutation is believed to happen at conception sporadically and permanently (since neither parent is affected). New mutations occur as a result of both genetic and environmental factors. They can be either chromosomal abnormalities or point mutations (specific alterations in the building blocks of genes called nucleotides). Research is ongoing to identify a more specific genetic mutation that causes HGPS.

Demographics

Occurrence of HGPS is sporadic and rare, although studies suggest frequency may be related to increased parental age and increased average difference in age of parents. Approximately 200 cases have been reported to date in the world, with the estimated prevalence being 1 in 4 to 8 million.

Signs and symptoms

HGPS is progressive. The following signs develop over time:

- **General**—Patients are short and weigh less than is appropriate for height. Patients usually do not grow taller than 3.7 ft. (1.15 m) or weigh over 40 lb (15 kg). Patients with HGPS do not usually exhibit mental impairment.
- **Skin**—Skin is usually thin, dry, and wrinkled. The skin in the hands and feet is pushed inward. The skin also exhibits color (pigmentation) changes, which present clinically as yellow-brownish spots. Patients also have a decrease in fat below the skin (subcutaneous) except in

KEY TERMS

Arteriosclerosis—Hardening of the arteries that often results in decreased ability of blood to flow smoothly.

Failure to thrive—Significantly reduced or delayed physical growth.

Progeria—Genetic abnormality that presents initially as premature aging and failure to thrive in children.

Scleroderma—A relatively rare autoimmune disease affecting blood vessels and connective tissue that makes skin appear thickened.

the area below the navel. The nails of patients with HGPS are small, thin, and poorly developed. Patients experience alopecia (hair loss) of the scalp, eyelashes, and eyebrows. Scalp veins become visible and prominent as hair loss progresses.

- **Bones**—There are several abnormalities in the skeletal structure.
- **Eyes**—Patients often appear to have prominent eyes. This is in part secondary to the alterations in bone structure of the face. Patients also may experience farsightedness (hyperopia) and astigmatism. Astigmatism is the changes in the structure of the lens and cornea (parts of the internal structure of the eyes) that alter the eyes' ability to focus incoming visual images.

Diagnosis

Diagnosis is based upon physical appearance. It is usually made within the first two years of life when patients develop skin changes and fail to grow.

Patients with HGPS eventually develop skeletal system (bone and joint) changes. Patients show characteristic radiographic (x-ray) findings. In general the skeleton is hypoplastic (underdeveloped). Patients have persistent anterior fontanelles (soft spots of skull in newborn children). Patients with HGPS may also develop deterioration of the collarbone and ends of the fingers. Hip joints are affected because of alteration in the bone structure of the femur (the bone that extends from the knee upward to the pelvis). This causes the femur to sit in more of a straight-line relationship to the hip joint. This is abnormal and causes a wide-based gait (walking) and the appearance of a horse-riding stance. It is described as coxa valga. Some patients also show an increase in the amount of hyaluronic acid secreted in the urine. Hyaluronic acid is a substance in the body that is found in tissues such

QUESTIONS TO ASK YOUR DOCTOR

- What are the symptoms and signs by which HGPS can be recognized?
- What do scientists know about the genetic basis of HGPS?
- Are there medications or other treatments that can be used to alter the rate at which HGPS progresses?
- What organizations provide additional information and/or support services for parents of children with HGPS?

as cartilage. Cartilage is a flexible connective tissue that works as a joint stabilizer.

Treatment and management

There is no cure for HGPS. Treatment is symptomatic and aimed at providing psychological support. Palliative measures such as wearing a wig may be beneficial. Relief from chest pain due to changes in arteries can be accomplished by nitroglycerin, which is a medication that relaxes muscle fibers in blood vessels, causing them to expand or dilate. This permits proper blood flow to affected areas, which enables cells and tissues to receive adequate amounts of the oxygen necessary for cell maintenance.

Experimental research management

Recent evidence suggests the benefit of giving nutritional therapy and growth hormone supplementation. The combination treatment of nutritional therapy and growth hormone supplementation demonstrated an increase in growth of HGPS patients, an increase in growth factors (chemicals that promote formation) within the blood, and a decrease in the patients' basal metabolic rates. Basal metabolic rate is the minimum amount of energy (calories) that an individual needs to ingest on a daily basis in order to execute normal activities and tasks. Cruciferous vegetables may also be a utilized nutritional therapy, as sulforaphane (SFN), an antioxidant found in these leafy greens, have been shown to clear progerin buildup in cells and decrease signs and symptoms of the syndrome. This finding may lead to increased therapies with sulforaphane itself as well.

Testing for drug treatment of this disease and even reversal of the disorder *in vitro* is currently ongoing. This treatment includes the use of statins and

farnesyltransferase inhibitors to decrease the amount of progerin in the body. These drugs have reduced the amount of changes to the nuclear rim of cells, increasing the lifespan of individuals with HGPS and also decreasing the severity of the symptoms. These drugs are not yet approved by the FDA.

Arteriosclerosis is most prominent in coronary (heart) arteries and the aorta (the largest artery in the body, which has many branches supplying oxygen-filled blood to cells and tissues). Research indicates successful outcome from aggressive treatment of arteriosclerosis utilizing techniques such as coronary artery bypass (reconstruction of the heart arteries) or coronary artery balloon dilation (stretching the heart arteries in an attempt to allow increased blood flow).

Prognosis

Age of death ranges from 7 to 27 years. One documented case reports an individual living to be 45 years of age. Death is usually secondary to arteriosclerosis complications such as heart failure, myocardial infarction (heart attack), or coronary thrombosis (when a clot from the heart moves to another location, cutting the flow of blood to the new location).

Hydrocephalus

Definition

Hydrocephalus is an abnormal expansion of cavities (ventricles) within the brain that is caused by the accumulation of cerebrospinal fluid. Hydrocephalus comes from two Greek words: *hydros* means “water” and *cephalus* means “head.”

There are two main varieties of hydrocephalus: congenital and acquired. An obstruction of the cerebral aqueduct (aqueductal stenosis) is the most frequent cause of congenital hydrocephalus. Acquired hydrocephalus may result from spina bifida, intraventricular hemorrhage, meningitis, head trauma, tumors, and cysts.

Description

Hydrocephalus is the result of an imbalance between the formation and drainage of cerebrospinal fluid (CSF). Approximately 500 milliliters (1 pint) of CSF is formed within the brain each day, by ependymal cells in structures collectively called the choroid plexus. These cells line chambers called ventricles that are located within the brain. There are four ventricles in a human brain. Once formed, CSF usually circulates among all the ventricles before it is absorbed and returned to the circulatory system. The normal adult volume of circulating CSF is 150 milliliters. The CSF turnover rate is more than three times per day. Because production is independent of absorption, reduced absorption causes CSF to accumulate within the ventricles.

Hydrocephalus may be present at birth (congenital) or acquired. Congenital hydrocephalus may be caused by events that occur during fetal development or by genetic abnormalities. Acquired hydrocephalus develops at the time of birth or at some point afterward. It can affect persons of all ages and may be caused by injury or disease. Hydrocephalus is usually described as “communicating” or “noncommunicating.” Noncommunicating hydrocephalus is the most common variety, caused by reduced CSF absorption that occurs when one or more passages connecting the ventricles become blocked. This prevents the movement of CSF to its drainage sites in the subarachnoid space just inside the skull. In communicating hydrocephalus, a reduction in the CSF absorption rate is caused by damage to the absorptive tissue.

Both types of hydrocephalus lead to an elevation of the CSF pressure within the brain. The increased pressure pushes aside the soft tissues of the brain. This squeezes and distorts them. This process also results in damage to these tissues. In infants whose skull bones have not yet fused, the intracranial pressure is partly relieved by

expansion of the skull so that symptoms may not be as dramatic. Both types of elevated-pressure hydrocephalus may occur from infancy to adulthood.

There are two other types of hydrocephalus that primarily affect adults: normal-pressure hydrocephalus and hydrocephalus ex-vacuo. Normal-pressure hydrocephalus is characterized by ventricle enlargement without an apparent increase in CSF pressure. This type affects mainly the elderly. Hydrocephalus ex-vacuo occurs when stroke or traumatic injury damage the brain.

Hydrocephalus has a variety of causes including the following:

- congenital brain defects
- hemorrhage, either into the ventricles or the subarachnoid space
- infection of the central nervous system (syphilis, herpes, meningitis, encephalitis, or mumps)
- tumor

Genetic profile

A growing body of evidence suggests that genetic factors play a major role in congenital hydrocephalus. Genetic studies in animal models have helped understand the underlying pathology of the condition. At least 43 mutants/loci linked to hydrocephalus have been identified in animal models and humans. In animal models, nine genes associated with hydrocephalus have been identified. Molecular genetic studies have shown that the responsible gene for human congenital hydrocephalus is located at Xq28 encoding for *LICAM* (L1 cell adhesion molecule).

The *LICAM* gene provides instructions for producing the L1 protein, found throughout the nervous system on the surface of neurons. It is a trans-membrane protein, meaning that it spans across the cell membrane and plays an important role in the development and organization of neurons, the formation of the protective sheath (myelin) that surrounds nerve fibers, and the formation of junctions between nerve cells (synapses) that allow cell-to-cell communication. Some 200 mutations of this gene have been associated with L1 syndrome, a disorder characterized by muscle stiffness (spasticity) of the lower limbs, intellectual disability, hydrocephalus, and thumbs bent toward the palm (adducted thumbs).

Demographics

The incidence of hydrocephalus is difficult to establish since there is no national registry or database of people with the condition. According to the National Institute of Neurological Disorders and Stroke (NINDS), hydrocephalus is believed to occur in approximately 1 of every

Transillumination of the head of an infant suffering from hydrocephalus. Yellow areas show fluid accumulation inside the skull that has caused enlargement of the baby's head. To prevent brain damage, the fluid must be drained by means of a tube (shunt) inserted through a hole in the skull; surgery is usually successful. (Alfred Benjamin/Science Source)

500 live births. The incidence of adult-onset hydrocephalus is not known.

Signs and symptoms

Signs and symptoms of elevated-pressure hydrocephalus include the following:

- headache
- nausea and vomiting, especially in the morning
- lethargy
- disturbances in walking (gait)
- double vision
- subtle difficulties in learning and memory
- delay in children achieving developmental milestones

Irritability is the most common sign of hydrocephalus in infants. If this is not treated, it may lead to lethargy. Bulging of the fontanelles, or the soft spots between the skull bones, may also be an early sign. When hydrocephalus occurs in infants, fusion of the skull bones is prevented. This leads to abnormal expansion of the skull.

Symptoms of normal-pressure hydrocephalus include dementia, gait abnormalities, and incontinence (involuntary urination or bowel movements).

Diagnosis

Imaging studies—x-ray, computed tomography scan (CT scan), ultrasound, and especially magnetic resonance imaging (MRI)—are used to assess the presence and

KEY TERMS

Cerebral ventricles—Spaces in the brain that are located between portions of the brain and filled with cerebrospinal fluid.

Cerebrospinal fluid—Fluid that circulates throughout the cerebral ventricles and around the spinal cord within the spinal canal.

Choroid plexus—Specialized structures located in the ventricles of the brain that produce cerebrospinal fluid.

Fontanelle—One of several “soft spots” on the skull where the developing bones of the skull have yet to fuse.

L1 syndrome—Inherited disorder that primarily affects the nervous system caused by mutations in the *L1CAM* gene. L1 syndrome involves a variety of features including muscle stiffness (spasticity) of the lower limbs, intellectual disability, hydrocephalus, and thumbs bent toward the palm (adducted thumbs).

Neuron—A nerve cell that sends and receives electrical signals over long distances within the body.

Shunt—A small tube placed in a ventricle of the brain to direct cerebrospinal fluid away from the blockage into another part of the body.

Stenosis—The constricting or narrowing of an opening or passageway.

Subarachnoid space—The space between two membranes surrounding the brain, the arachnoid and pia mater.

location of obstructions, as well as changes in brain tissue that have occurred as a result of the hydrocephalus. Lumbar puncture (spinal tap) may be performed to aid in determining the cause when infection is suspected.

Treatment and management

The primary method of treatment for both elevated and normal-pressure hydrocephalus is surgical installation of a shunt. A shunt is a tube connecting the ventricles of the brain to an alternative drainage site, usually the abdominal cavity. A shunt contains a one-way valve to prevent reverse flow of fluid. In some cases of noncommunicating hydrocephalus, a direct connection can be made between one of the ventricles and the subarachnoid space, allowing drainage without a shunt.

QUESTIONS TO ASK YOUR DOCTOR

- Your tentative diagnosis is that our infant has hydrocephalus. On what is this diagnosis based?
- What tests are available to confirm your diagnosis?
- What treatments or procedures are available for our child's condition?
- Should my spouse and I decide to have more children, what is the risk that they will also have hydrocephalus?

Installation of a shunt requires lifelong monitoring by the recipient or family members for signs of recurring hydrocephalus due to obstruction or failure of the shunt. Other than monitoring, no other management activity is usually required.

Some drugs may postpone the need for surgery by inhibiting the production of CSF. These include acetazolamide and furosemide. Other drugs that are used to delay surgery include glycerol, digoxin, and isosorbide.

Some cases of elevated-pressure hydrocephalus may be avoided by preventing or treating the infectious diseases that precede them. Prenatal diagnosis of congenital brain malformation is often possible.

Clinical trials

Clinical trials on hydrocephalus are currently sponsored by the National Institutes of Health (NIH) and other agencies. As of 2015, there were three trials reported as under way by NIH. Examples of studies include the following:

- a study to determine which combination of tests will enable physicians to predict whether a patient with symptoms of normal-pressure hydrocephalus will improve with a shunt (NCT00613886)
- the evaluation of a new procedure, endoscopic third ventriculostomy (ETV), to treat hydrocephalus (NCT00652470)
- the Core Data Project, which aims to obtain data about all neurosurgical hydrocephalus events from a network of clinical centers to help investigators understand the variability, progression, and current treatment practices for hydrocephalus in children, with an ultimate goal of better guiding and assessing therapeutic intervention and

providing recommendations on patient care (NCT00670735)

- the evaluation of an ultrasonic flow sensor to accurately measure flow in hydrocephalic shunts (NCT00652197)

Clinical trial information is constantly updated by NIH and the most recent information on hydrocephalus trials can be found at <http://www.clinicaltrials.gov>

Prognosis

The prognosis for elevated-pressure hydrocephalus depends on a wide variety of factors, including the cause, age of onset, and the timing of surgery. Studies indicate that about half of all children who receive appropriate treatment and follow-up will develop IQs greater than 85. Those with hydrocephalus at birth do better than those with later onset due to meningitis. For individuals with normal-pressure hydrocephalus, approximately half will benefit from the installation of a shunt.

Hydrolethalus syndrome 1 (HLS1)

Definition

Hydrolethalus syndrome 1 (HLS1) is a rare and primarily lethal disorder characterized by severe birth defects and stillbirth.

Description

HLS1 is a congenital condition characterized by multiple birth defects including hydrocephalus (excess fluid in the brain), polydactyly (extra fingers and toes), incomplete lung development, and anomalies of the brain, heart, face, lip, and palate. The birth defects are typically extreme enough to cause stillbirth or death within a few days of birth. A less common name for HLS1 is Salonen-Herva-Norio syndrome, after the Finnish researchers who first described it in 1981.

Genetic profile

HLS1 is caused by mutations in the *HYLS1* gene, which carries instructions for proteins that are contained in the cytoplasm of the cell. It is unclear how mutations in the *HYLS1* gene cause the malformations that are characteristic to HLS1.

Mutations in the *HYLS1* gene are inherited in an autosomal recessive pattern. Autosomal means that the syndrome is not carried on a sex chromosome, while recessive means that both parents must carry the gene mutation in order for their child to have the disorder. Some cases of HLS1 have been observed where the parents are related by blood (consanguineous). Parents with one child affected by HLS1 have a 25% chance that their next child will also be affected with the disease.

Each parent passes 23 chromosomes, or units of genetic information, to the infant. Structurally, each chromosome has a short segment or “arm,” called the p arm, and a long arm, called the q arm, extending from a central region called the centromere. Along each arm the chromosome is further divided by numbering the bands down the arm according to their appearance under a microscope. Each band corresponds to specific genes. Based on studies of genetic material from affected and nonaffected families, the gene location for HSL1 was determined to be 11q23-25, or somewhere between the 23rd and 25th band of the q arm of chromosome 11.

Demographics

The majority of cases of HLS1 have been reported in people of Finnish ancestry. In Finland the incidence of

KEY TERMS

Atrioventricular communis defect—A birth defect of the heart in which the canal between the upper and lower chambers of the heart does not form correctly.

Congenital—Present at birth.

Cytoplasm—The fluid inside a cell.

Foramen magnum—The round opening at the base of the skull through which the spinal cord passes to join the spine.

Sex chromosome—Genes that carry the information that determines gender.

HLS1 is estimated at 1 in every 20,000. Fewer than 20 cases have been reported outside of Finland.

HLS1 affects fetal development in the womb and is a syndrome of infants only, due to the extremely serious birth defects caused by the disorder. No cases of survival into childhood or adulthood have been reported. The syndrome appears to affect both males and females with equal probability.

Signs and symptoms

Prenatal symptoms include hydramnios, an excess of amniotic fluid in the womb. Babies with HLS1 are often delivered preterm and may be stillborn.

All or most of the following congenital anomalies are seen in HLS1:

- Hydrocephalus—Excess fluid in the brain
- Heart defects—Atrioventricular communis defect
- Pulmonary hypoplasia—Incomplete development of the lungs
- Polydactyly—Extra fingers and toes specifically, an extra big toe and an extra little finger on both hands and feet
- Club foot—Abnormally positioned, inwardly turned feet
- Cleft lip or palate—An opening in the lip and/or palate
- Micrognathia—Small lower jaw
- Hypoplastic (small) eyes
- Nose—Poorly formed
- Keyhole-shaped foramen magnum—A keyhole shaped defect at the base of the skull
- Abnormal genitalia—Abnormal sex organs

QUESTIONS TO ASK YOUR DOCTOR

- What are the chances that I will have another baby with HLS1?
- Is there a prenatal test to see whether my baby has HLS1?
- Is there a way to prevent HLS1?
- Should my partner and I have a family history screening?

Diagnosis

HLS1 can be diagnosed prenatally by ultrasound scanning in as early as the 11th week of gestation. After birth, the presence of multiple malformations, especially the extreme swelling of the skull and other brain and spinal cord defects, can confirm the diagnosis. A family history and genetic testing may be useful in making the diagnosis certain.

Treatment and management

There is no treatment for HLS1 other than management of the specific medical conditions and providing care and comfort to the infant. The severity of symptoms almost always causes death of the infant within a few days of birth, that is if the fetus survives to full term.

Genetic counseling is particularly important in the prenatal treatment and management of HLS1 and to help parents plan subsequent pregnancies.

Prognosis

The prognosis for infants with HLS1 is extremely poor. Most affected infants are stillborn or die within the first day of life. Only a handful of cases of survival past the neonatal period have been reported, and the longest survival period was 44 days.

Hydrometrocolpos syndrome see **McKusick-Kaufman syndrome**

Hydrops fetalis

Definition

Hydrops fetalis (HF) refers to the abnormal accumulation of fluid in the skin, body cavities, umbilical cord, and placenta of an unborn baby. HF can result from many different diseases and structural defects. It is traditionally divided into two major categories: immune HF and non-immune HF. Immune HF is caused by Rh incompatibility, which was the most common cause of HF until the advent of anti-Rh antibody treatment (RhoGAM) during pregnancy. All other causes of HF are termed nonimmune HF. Nonimmune hydrops fetalis (NIHF) may be caused by chromosomal aberrations, other genetic disorders, infections, anemias, such structural birth defects as congenital heart disease, and many other conditions.

Description

HF occurs when a baby has a condition or birth defect that causes accumulation of excess fluid, known as edema, in the skin and other body cavities. Immune HF occurs when a mother's blood group is Rh-negative (this term means that she does not have the Rh factor [protein] on the surface of her blood cells) and her baby's blood group is Rh-positive (the baby has the Rh protein on its blood cells). During the pregnancy a small amount

of the baby's blood crosses into the mother's circulatory system. When this exchange happens, the mother's immune system recognizes the Rh protein on the baby's blood cells as foreign and makes antibodies to the Rh protein. The antibodies can then cross back over to the baby and attack its blood cells, destroying them and causing anemia. The anemia causes heart failure, subsequent edema, and ultimately HF. The mother's immune response becomes greater with each subsequent pregnancy in which the baby has Rh-positive blood and thus the HF becomes worse. Administration of anti-Rh antibodies during all of an Rh-negative mother's pregnancies will prevent her from ever developing an immune response to Rh-positive blood and will prevent HF.

The most common causes of nonimmune HF include heart disease (congenital malformations and arrhythmia), chromosome aberrations (Turner syndrome and Down syndrome), other genetic disorders that cause anemia (particularly alpha thalassemia), and anemia caused by other disorders (fetomaternal transfusion and twin-twin transfusion). Other causes include infections, metabolic disorders, and tumors. In all there are over 100 separate causes of nonimmune HF.

All disorders that cause HF do so by three common mechanisms that include heart failure, hypoproteinemia (low levels of protein in the bloodstream), and vascular or lymphatic obstruction. Some disorders combine two or more of these mechanisms to cause HF. Most disorders cause some degree of heart failure. Anemia causes heart failure by increasing the work of the heart so much that it fails (high-output heart failure). Isolated congenital heart disease or conditions that have congenital heart disease as a feature often develop heart failure due to a poorly functioning heart (low-output heart failure). Conditions that block the flow of blood or lymph can cause edema and HF. Examples include tumors and congenital malformations of the blood and lymphatic vessels. Conditions that lower the amount of protein in the blood can cause edema and HF by allowing fluid to easily leak out of the vessels and collect in the soft tissues and body cavities. Examples include metabolic conditions that damage the liver and prevent it from producing enough protein, such as Gaucher disease and Sly disease.

Genetic profile

Many causes of HF do not have a genetic etiology. Because the recurrence risk can range from 0% to 100% depending on the underlying cause, an accurate diagnosis is important. Infectious causes are not genetic and should not recur in subsequent pregnancies. Other causes of HF have a specific genetic profile. Immune causes are due to a difference in the antigens on the mother's and baby's blood cells, which can recur in subsequent pregnancies if

anti-Rh antibodies are not given to the mother. Recurrence can either be 50% or 100% depending on the father's Rh-antigen status.

If HF is caused by a chromosome aberration, the risk of recurrence is about 1%, as most of these conditions occur sporadically and are not inherited.

Malformations causing HF, such as congenital heart disease, are most commonly inherited as multifactorial traits. This type of inheritance pattern is caused by multiple genes and environmental factors working in combination. The recurrence risk for a multifactorial trait is about 3%–5% with each subsequent pregnancy.

Higher risk of recurrence occurs when a single gene condition is the cause of HF. Such autosomal recessive conditions as alpha thalassemia major, Gaucher disease, and Sly disease have a recurrence risk of 25% with each subsequent pregnancy. The X-linked recessive disorder G-6-P-deficiency has a recurrence risk of 50% with each additional male child and 0% with each additional female child.

Some dominant conditions can cause HF; these are often lethal and usually represent a new mutation in that child. In these cases the recurrence risk is about 1%. Other dominant conditions such as myotonic dystrophy and lymphedema distichiasis are variable; recurrence may be 50% with each child.

Demographics

The incidence of common HF in the United States is estimated at 1 in 600 to 1 in 4,000 pregnancies. The incidence of immune hydrops has significantly decreased with the wide use of passive immunization using Rh immunoglobulin for Rh-negative mothers at 28 weeks gestation and postpartum. This program has resulted in a decline in the incidence of Rh-hemolytic disease of the fetus or newborn, from 65 in 10,000 births in the United States in 1960 to 6.7 in 10,000 births in 2002.

HF is much more common in Southeast Asia and North Africa. In Thailand, the expected frequency of hydrops from homozygous alpha thalassemia or Bart's hydrops alone is 1 in 500 to 1 in 1,500 pregnancies. Bart's hydrops, also known as Hb Bart's syndrome, is the most severe form of alpha thalassemia and is marked by frequent miscarriage of the affected pregnancy or the death of the baby shortly after birth. Accurate reports from the Mediterranean region are lacking; however, the commonness of glucose-6-phosphate dehydrogenase (G-6-PD) deficiency and of defects in alpha-chain hemoglobin production in several populations from this region suggest that the incidence of HF is higher than it is in the United States. The single exception is California, which

KEY TERMS

Alpha thalassemia—A genetic disorder in which mutations in the *HBA1* and *HBA2* genes on chromosome 16 lead to impaired production of a subtype of hemoglobin known as alpha globin. The severity of the disorder depends on how many of the four alpha globin chains are affected by mutations.

Autosomal dominant—A pattern of genetic inheritance in which only one abnormal gene is needed to display the trait or disease.

Edema—An abnormal accumulation of fluid beneath the skin and in the cavities of the body.

G-6-P deficiency—An X-linked genetic disorder that predisposes patients to the spontaneous destruction of red blood cells in response to certain triggers that include certain foods, medications, and illnesses. It is caused by a mutation on the X chromosome at Xq28.

Gaucher disease—A genetic disorder characterized by the accumulation of fatty substances in certain cells and organs. It is caused by a mutation in a gene on chromosome 1 and is inherited in an autosomal recessive pattern. It is named for the French physician Philippe Gaucher, who first described it in 1882.

Hb Bart's syndrome—The form of alpha thalassemia most likely to cause hydrops fetalis in the fetus. The name of the syndrome refers to a defective type of hemoglobin (Hb) that has almost no ability to carry oxygen to the fetus's tissues and to the hospital in London (St. Bartholomew's, or Bart's) where the syndrome was first identified.

Indirect Coombs test—A test given to pregnant women to detect the presence of circulating antibodies against red blood cells.

Lymphedema distichiasis—A genetic syndrome caused by a mutation in the *FOXC2* gene on chromosome 16 and characterized by localized fluid

retention and swelling of the limbs (lymphedema) and a double row of eyelashes (distichiasis).

Myotonic dystrophy—A chronic progressive multi-system disease characterized by general muscular weakness, cataracts, and changes in the endocrine system. It is inherited in an autosomal dominant pattern and is caused by mutations in either the *DMPK* gene on chromosome 19 or the *ZNF9* gene on chromosome 3.

Rh factor—An inherited trait that refers to a protein found on the surface of red blood cells. A person whose blood cells have the protein is said to be Rh-positive; a person whose blood cells lack the protein is Rh-negative. "Rh" stands for Rhesus, the species of monkey used in the medical research that led to the discovery of the Rh factor.

RhoGAM—The trade name of a medication given by intramuscular injection to a pregnant woman to prevent Rh disease in the newborn. Its generic name is Rho (D) immune globulin.

Sly disease—Also called Sly syndrome, an autosomal recessive lysosomal storage disease caused by a mutation in a gene on chromosome 7. It is named for William Sly, the American biochemist who discovered it.

Toxemia of pregnancy—A condition characterized by high blood pressure and large amounts of protein in the urine. It is also called pre-eclampsia. If left untreated, it may result in the breakdown of red blood cells, liver and kidney dysfunction, and seizures.

Turner syndrome—A genetic disorder in which a female has only one normal X chromosome due to a chromosomal abnormality in which all or part of the second X chromosome is missing.

has experienced a high rate of immigration from Southeast Asia and North Africa in recent years.

Signs and symptoms

All babies with HF have edema of the skin, soft tissues, and placenta. Often the body cavities (including the abdominal cavity [ascites], pleural cavity, and pericardial cavity) will show fluid collections. The back of the neck is particularly prone to fluid collections and can sometimes contain so much fluid that it appears as a large cystic mass called a cystic hygroma. Such internal organs as the liver, spleen, and heart can become enlarged with

accumulated fluid. All of these signs may be seen in the newborn or before birth using ultrasonography.

Other signs of HF are variable and often depend on the underlying cause. Common to most causes of HF are decreased movements during the pregnancy, respiratory distress from poor lung development due to compression of the lungs by accumulated fluid, and heart failure.

Diagnosis

HF is easily diagnosed at birth by the swollen appearance of an affected baby, but the diagnosis is often

QUESTIONS TO ASK YOUR DOCTOR

- How common are the various forms of nonimmune HF in the general American population?
- How early during pregnancy can nonimmune HF be detected?
- Should I or other family members consider genetic testing for alpha thalassemia or the other genetic syndromes associated with HF?
- Can you recommend a nearby medical center with special expertise in delivering infants diagnosed with HF?

made during the pregnancy by ultrasonography. Determining the cause of the HF is more challenging, but necessary, for possible treatment and recurrence risk assessment. The Society for Maternal-Fetal Medicine (SMFM) recommends first administering an antibody screen known as an indirect Coombs test to determine whether the HF is nonimmune. Testing the mother for infections such as toxoplasmosis, rubella, cytomegalovirus (CMV), herpes, syphilis, and parvovirus B19 can rule out most infectious causes of HF. A high-resolution ultrasound will help determine if a baby has any major structural malformations or tumors that could cause HF. At the same time as the ultrasound, a percutaneous umbilical artery blood sampling (PUBS) procedure can be done. This procedure consists of passing a needle through the mother's abdomen into the uterine cavity and then into the baby's umbilical cord to withdraw a small amount of blood. This blood is then used to test for Rh antibodies, anemia, chromosome aberrations, and other suspected conditions. Molecular genetic testing for Hb Bart's syndrome is available at the molecular diagnostics laboratory at the University of California, San Francisco. These diagnostic steps determine the cause of the HF in many cases, but sometimes the cause remains unknown.

Treatment and management

Immune HF is easily prevented by administration of anti-Rh antibodies to Rh-negative pregnant women. Most nonimmune HF causes have no specific treatment other than early delivery and supportive care. The SMFM recommends delivery at a specialized facility with experience in stabilizing and treating critically ill newborns. HF associated with alpha thalassemia is often treated by termination of the pregnancy, as the fetus is unlikely to survive until birth and the mother is at risk for severe complications of the pregnancy, including toxemia of pregnancy (pre-eclampsia). HF caused by some types of

anemia can be treated by a blood transfusion via a PUBS procedure. Fetal arrhythmia can often be treated by antiarrhythmic medications taken by the mother. Fetal operations are indicated for HF caused by sacrococcygeal teratomas (a type of tumor seen in newborns) and some other structural malformations.

Prognosis

The prognosis of HF is poor. A baby who is diagnosed by ultrasonography before birth has a less than 30% chance of survival. Babies who are born alive have a 50% chance of survival. The specific cause of HF influences the chances of survival, with chromosome aberrations and alpha thalassemia having a higher mortality rate, and infectious etiologies having a lower mortality rate.

Hyperlipoproteinemia

Definition

Hyperlipoproteinemia refers to a group of acquired and inherited disorders whose common denominator is excessive levels of lipids (fats) in the blood caused by a metabolic disorder. It is also referred to as hyperlipidemia. The condition is a major cause of coronary heart disease (CHD).

Description

The acquired form of hyperlipoproteinemia occurs as a condition secondary to another disease, such as diabetes mellitus, hypothyroidism, or nephrosis. The hereditary, or inherited, form of hyperlipoproteinemia is classified into five major types.

Lipids are an essential part of human metabolism and are a primary source of energy for the body. Lipids are produced by cells in the body and, along with carbohydrates and proteins, are components of all life. Lipids are essentially oil-based and as such do not mix with a water-based liquid such as blood. Yet both must be carried through the body's circulatory system. So to get around this obstacle, lipids attach themselves to proteins. This combination of lipids and proteins is called lipoproteins, which are water-soluble particles that can be carried through the bloodstream.

Some of the chemicals in the lipoproteins are fatty nutrients that are absorbed by the intestines for use in other parts of the body. Cholesterol is carried by lipoproteins through the bloodstream to the liver and ultimately to the bowel for excretion. If the substances in the lipoproteins are not properly balanced, cholesterol will stay in the tissues instead of being excreted. It can also build up in blood vessels, eventually restricting and even blocking blood flow.

There are five different densities of lipoproteins, each containing triglycerides, cholesterol, phospholipids (lipids with phosphorus attached), and special proteins. The lipoproteins are high-density lipoproteins (HDL), low-density lipoproteins (LDL), intermediate-density lipoproteins, very low-density lipoproteins (VLDL), and chylomicrons. HDL is commonly called "good" cholesterol and LDL "bad" cholesterol. The two major lipoprotein groups are HDL and LDL.

HDL helps prevent fat buildup throughout the body by carrying cholesterol from the arteries to the liver, where it is disposed of. Abnormally low levels of HDL, fewer than 30 milligrams per deciliter (mg/dL) of blood, are associated with a greater risk for coronary heart disease and stroke. LDL carries most of the cholesterol in

the body, so an excess of LDL, usually 160 mg/dL of blood, can clog the arteries with cholesterol buildup. This can lead to atherosclerosis, commonly referred to as hardening of the arteries, or acute myocardial infarction (heart attack).

The five types of inherited hyperlipoproteinemia are as follows:

- Type I, characterized by high levels of chylomicrons and triglycerides and a deficiency of lipoprotein lipase, an enzyme that accelerates the breakdown of lipoproteins. Disease onset is usually in infancy.
- Type II, broken into two subtypes, type II-a and type II-b. Both subtypes display high levels of blood cholesterol. People with type II-b also have high levels of triglycerides in their blood. Disease onset is usually after age 20.
- Type III, also called broad beta disease, is characterized by high blood levels of cholesterol and triglycerides and the presence of a lipoprotein called apolipoprotein E (ApoE) genotype E2/E2. Disease onset is usually in adults.
- Type IV, characterized only by high triglyceride levels in the blood. Disease onset is usually during puberty or early adulthood.
- Type V, characterized by increased blood levels of chylomicrons and triglycerides and low levels of LDL and HDL. Disease onset is usually in children or adults.

Genetic profile

As of 2015, type I hyperlipoproteinemia was considered to be due to a mutation in the *LPL* and *APOC-II* genes, as opposed to an autosomal dominant disorder as previously thought. These genes have a role in the activity of cholesterol and the removal of visceral fat.

Type III hyperlipoproteinemia is an autosomal recessive disorder that affects males and females. "Autosomal" means that the gene does not reside on the sex chromosome. People with only one abnormal gene are carriers, but since the gene is recessive, they do not have the disorder. Their children could be carriers of the disorder but not show symptoms of the disease. Both parents must have one of the abnormal genes for a child to have symptoms of type III hyperlipoproteinemia. When both parents have the abnormal gene, there is a 25% chance that each child will inherit both abnormal genes and have the disease. There is a 50% chance that each child will inherit one abnormal gene and become a carrier of the disorder but not have the disease itself. There is a 25% chance that each child will inherit neither abnormal gene and not have the disease or be a carrier.

KEY TERMS

Cholesterol—A steroid alcohol $C_{27}H_{45}OH$ present in animal cells and body fluids that regulates membrane fluidity, functions as a precursor molecule in various metabolic pathways, and functions as a constituent of LDL; it may cause arteriosclerosis.

Hyperlipoproteinemia—An increase in the amount of lipoproteins in the body.

Lipids—Any of various substances that are soluble in nonpolar organic solvents (as chloroform and ether) that with proteins and carbohydrates constitute the principal structural components of living cells, and that include fats, waxes, phospholipids, cerebroside, and related and derived compounds.

Lipoprotein—A complex protein that carries lipids throughout the body.

Type III hyperlipoproteinemia is a mutation in the production of *ApoE*, an apolipoprotein that has a role in the uptake of types of fat in the liver. The *ApoE* gene is located on the long arm of chromosome 19. When this protein is not functioning correctly, it will not remove the fat from the liver, hence a buildup of cholesterol in the body.

The other types of hyperlipoproteinemia are autosomal dominant. This means that they occur when an abnormal gene from one parent is capable of causing the disease even though the matching gene from the other parent is normal. The abnormal gene dominates the outcome of the gene pair. This means that there is a 50% chance that each child of the couple will have the disease. Consequently, there is a 50% chance that each child will not inherit the defective gene and will not have the disease.

Demographics

Hyperlipoproteinemia can affect people regardless of age, gender, race, or ethnicity; however, hyperlipoproteinemia III is known to affect males more than females. All adults, starting at age 20, should be tested for hyperlipoproteinemia at least once every five years, as recommended by the National Cholesterol Education Program (NCEP) of the National Institutes of Health (NIH). People considered to be high risk for hyperlipoproteinemia should be tested more often and include those with a diet high in fat and cholesterol, who have a family history of the disorder, who use oral contraceptives or take estrogen, or who have diabetes mellitus, hypothyroidism,

nephrosis, or alcoholism. Ethnic groups that have a higher risk of developing hyperlipoproteinemia include Latinos, Native Americans, African Americans, and Pacific Islanders.

Signs and symptoms

It is very common for people with hyperlipoproteinemia to show no outward signs of the disorder. However, there are several general signs that may indicate a person has the disorder, including obesity; yellowish skin; fatty yellow patches or nodules on the skin, especially the eyelids, neck, and back; inflamed tendons; an enlarged spleen; an inflamed pancreas; nausea and vomiting; or abdominal pain. However, these are also symptoms of a variety of other conditions, so for hyperlipoproteinemia to be diagnosed, blood tests are needed.

Diagnosis

Diagnosis involves a series of blood tests to measure lipid levels and determine the type of hyperlipoproteinemia. Blood tests, usually taken after a 12-hour fast, include measurement of total serum cholesterol, HDL, LDL, VLDL, and triglycerides, as well as measurement for the presence of apolipoprotein E. When hyperlipoproteinemia secondary to another disorder has been excluded and inherited hyperlipoproteinemia seems likely, first-degree relatives should be tested. These include parents, children, and siblings. The diagnosis for type I is made when at least three of the following criteria are met:

- clinical presentation of phenotype
- an apoprotein to B/LDL-C ration of less than 1.0 or the presence of small, dense LDLs
- secondary hyperlipidemia from another disease or disorder ruled out
- one or more immediate relatives diagnosed with types of hyperlipoproteinemia

The diagnosis for type III hyperlipoproteinemia is made with major criteria of increased serum cholesterol and serum TG levels, a change in the pattern of LDL and VLDL as seen on electrophoresis, abnormalities in *ApoE* as seen on electrophoresis with or without xanthoma, increased serum *ApoE*, a change in the ratio of VLDL to serum TG, a decreased level of LDL-C, and/or a diagnosis of cardiovascular disease(s).

Treatment and management

Hyperlipoproteinemia treatment is usually based on a threefold attack: diet, exercise, and lipid-lowering medications. People who are overweight should begin a program to slowly but consistently lose weight until they are at or near the recommended weight for their height

QUESTIONS TO ASK YOUR DOCTOR

- How often should I get bloodwork to check my levels?
- What type do I have, and what are the chances my children will be diagnosed with it as well?
- What dietary changes should I make?
- How long will I need to be on a diet?
- What complications should I be on the lookout for?
- How much exercise should I be doing daily/weekly, and what kind?
- Is there a prescription that is best for me?
- Is it possible for me to control this disorder without pharmaceuticals?

and body frame. It is essential to eat a diet low in fat. “Bad” cholesterol is found only in animal products, so eating a diet very low in meat, especially avoiding cow and pig products, and unhealthy oils, especially in fried foods, is extremely important. Exercise also plays a vital role. A minimum of 20 minutes of aerobic exercise three times a week is beneficial, and 30 minutes or more daily is ideal. The exercise can take the form of running, jogging, cycling, swimming, cardiovascular machines, or even walking briskly.

Eating healthy and exercising regularly, while extremely beneficial, are not always enough to bring lipid levels to the desired range. Prescription medications are often required. There is a wide range of medications available to manage lipid levels. The most prescribed are HMG-CoA-reductase inhibitors, commonly called “statins,” which hinder the body’s production of cholesterol. Statins include cerivastatin (Baycol), fluvastatin (Lescol), lovastatin (Mevacor), pravastatin (Pravachol), atorvastatin (Lipitor), and simvastatin (Zocor). Other first-line medications include bile acid sequestrants, cholestyramine (Questran), colesevelam (Welchol), and colestipol (Colestid). Also, probucol (Lorelco) is sometimes used.

The type of drug prescribed may vary, depending on the lipid test results and the type of hyperlipoproteinemia that is diagnosed. For example, people with type III of the disorder respond better when prescribed fibric acid derivatives such as gemfibrozil (Lopid), clofibrate (Atromid-S), and fenofibrate (Tricor) or nicotinic acid (niacin).

Case studies published as of 2015 reported that another form of treatment for hyperlipoproteinemia and prevention of cardiovascular disease have been

conclusive. This form of treatment is known as lipoprotein apheresis (LA). LA is a form of therapy in which blood is removed from the body and passed through a filter system that removes lipids and puts back in the clean blood. LA has been shown to be highly effective in the treatment and management of hyperlipoproteinemia and the prevention of cardiac events.

Other factors that have a negative effect on hyperlipoproteinemia include smoking, excessive alcohol consumption, and stress. It is important to treat underlying conditions, such as diabetes, heart disease, pancreatitis (inflamed pancreas), and thyroid problems.

Prognosis

The prognosis is good for type I hyperlipoproteinemia with treatment. For type II, the prognosis is good for II-b and fair for II-a with early diagnosis and treatment. The prognosis for type III is good when the prescribed diet is strictly followed. The prognosis is uncertain for types IV and V, due to the risk of developing premature coronary artery disease in type IV and pancreatitis in type V.

Hyperoxaluria

Definition

Hyperoxaluria occurs when a person's urine contains too much of a salt known as oxalate. Symptoms can range from kidney stones to kidney failure.

Description

Individuals with hyperoxaluria have an excess of oxalate in their urine. Oxalate is a salt of oxalic acid, which is found in many plants, such as spinach, soy beans, and coffee. The excess oxalate can have several causes, including its overproduction by the liver. The excess oxalate does not readily dissolve; instead, it combines with calcium in the urine to produce a compound called calcium oxalate. These calcium oxalate deposits can become kidney stones in the urinary tract.

For some patients, having kidney stones is the main and sometimes only symptom of hyperoxaluria. One-fifth to one-third of patients with recurring kidney stones have excess oxalate in their urine. In other patients, the concentration of oxalate is especially high and can lead to kidney damage and eventually kidney failure. When patients experience such kidney failure, they develop a condition known as oxalosis in which the overload of oxalate begins to gather elsewhere in the body, including the eyes, bones and muscles, circulatory system, and other organs, where it can cause damage. There are four main types of hyperoxaluria: primary hyperoxaluria (types, I, II, and III), enteric hyperoxaluria, dietary hyperoxaluria, and idiopathic or mild hyperoxaluria.

Individuals who have excess oxalate due to overproduction by the liver are said to have primary hyperoxaluria. Primary hyperoxaluria is a rare genetic disorder that causes the liver to make insufficient enzymes, which in turn causes the excess production of oxalate. In this form of hyperoxaluria, oxalate levels can be very high (200 mg/d or more). Primary hyperoxaluria occurs in three types: Type I primary hyperoxaluria, in which the liver makes too little of the enzyme known as alanine-glyoxylate aminotransferase (AGT); Type II primary hyperoxaluria, in which the liver is lacking the enzyme known as glyoxylate reductase/hydroxypyruvate reductase, or GR/HPR; and Type III primary hyperoxaluria, a less severe form of hyperoxaluria than primary type I or II that may be completely asymptomatic or limited to stone formation only. Primary type III may even improve over time, unlike primary hyperoxaluria type I or II.

The other types of hyperoxaluria include enteric hyperoxaluria, which is typically associated with chronic diarrhea, dietary hyperoxaluria, which is caused by a diet

heavy in oxalate-rich foods and animal proteins (such as meat), and idiopathic or mild hyperoxaluria, which may be related to diet or to unknown causes.

Genetic profile

Primary hyperoxaluria is the only type of hyperoxaluria with a known genetic origin. It is caused by mutations in the *AGXT* and *GRHPR* genes. Located on chromosome 2, the *AGXT* gene carries the blueprint for making the liver enzyme AGT. Scientists have identified over 50 mutations of this gene associated with type I primary hyperoxaluria. Mutations of the *AGXT* gene cause reduced production of AGT. Low levels of AGT lead to the accumulation of glyoxylate, which then converts to oxalate. Excess oxalate combines with calcium to form calcium oxalate and leads to the symptoms of primary hyperoxaluria type I, such as kidney stones, kidney damage, and kidney failure, and may possibly damage other organs as well.

The *GRHPR* gene is located on chromosome 9. It carries the blueprint for making the liver and kidney enzyme GR/HPR. Scientists have identified at least a dozen *AGXT* mutations associated with type II primary hyperoxaluria. Individuals who have inherited the mutated GR/HPR gene make insufficient GR/HPR. As with mutations on the *AGXT* gene, mutations in the *GRHPR* cause glyoxylate to build up and convert into excess oxalate, leading to the symptoms of primary hyperoxaluria type II.

Primary hyperoxaluria types I and II are inherited in an autosomal recessive pattern. For someone to be affected with an autosomal recessive disease, he or she must inherit two copies of an abnormal or mutated gene, one from each parent. A parent who has only one gene associated with an autosomal recessive condition is not affected by the disease and is known as a carrier of the disease. Two carriers of autosomal recessive mutated gene have a 25% chance of having a child affected with the disorder in each pregnancy.

Demographics

Primary hyperoxaluria is a rare genetic disorder. Both type I and type II are autosomal recessive disorders. According to the National Institutes of Health, Type I hyperoxaluria affects about one to three million people worldwide, with the highest incidence in Tunisia and some other Mediterranean countries. Most individuals with type I experience symptoms in late childhood to early adolescence, although some have their first symptoms soon after birth (this is sometimes called infantile type I), while others have their first symptoms in their mid-20s.

KEY TERMS

Biopsy—A medical procedure in which a small piece of tissue is removed so that it may be tested or examined.

Enzyme—Proteins within the body that cause chemical changes.

Kidney stones—Mineral depots that form inside the kidney.

Molecular genetic testing (gene tests)—Medical test that examines single genes or short lengths of DNA to identify changes or mutations that cause genetic disorders.

Oxalate—A naturally occurring molecule in the human body and in nature, too much of which can cause kidney stones.

Oxalosis—A metabolic process in the body that happens in patients with primary hyperoxaluria whose kidneys fail. When the body stops removing extra oxalate, it accumulates in the blood and organs and leads to serious complications.

Type II is even rarer than type I, although no estimate has been made of the number of people it affects. Symptoms typically first appear during the childhood years.

Signs and symptoms

Individuals with type I primary hyperoxaluria may begin to experience symptoms soon after birth or later in life, usually by about 25 years of age. About 1 in 10 develop symptoms before they are six months old, and they typically experience severe health problems including the following:

- Nephrocalcinosis, a disorder in which the concentration of calcium in the kidneys is too high
- Anemia, a disorder resulting from insufficient red blood cells or hemoglobin in the blood
- Metabolic acidosis, which is an unusually high acidity in the blood

The first symptoms of the remaining majority of individuals with type I primary hyperoxaluria typically are recurrent kidney stones. If left untreated, individuals with type I primary hyperoxaluria typically experience a continued decline in kidney function and eventual kidney failure with progression to oxalosis, possibly culminating with death from end-stage kidney disease.

Individuals with type II primary hyperoxaluria typically experience recurring kidney stones in childhood. If untreated, the disease progresses as it does with many type I patients: recurring kidney stones, decline in kidney function, eventual kidney failure, oxalosis, and death from end-stage kidney disease.

Diagnosis

Hyperoxaluria is diagnosed through the following methods.

Examination

Doctors may suspect primary hyperoxaluria if a patient, especially one younger than 25 years of age, experiences recurring kidney stones. To make a diagnosis, the doctor will order tests.

Tests

A doctor will order a urine and/or blood test to check for a high concentration of oxalate in the urine and or the blood plasma.

Procedures

In addition, a doctor may perform a liver biopsy to check for activity of the GR/HPR or AGT enzymes. The doctor may order molecular genetic testing, which scans the patient's DNA for the presence of the *GRHPR* or *AGXT* gene mutations.

Treatment and management

Treatment varies with the severity of the disorder.

Drugs

The doctor may prescribe regular, daily, high dosages of pyridoxine (vitamin B₆) to help reduce the amount of oxalate produced by the liver. The doctor may also recommend neutral phosphates, citrate, and/or magnesium to diminish kidney stone formation.

Dietary modifications

Patients may be advised to limit fats as well as certain foods that contain high levels of oxalate.

Other

The doctor may suggest that some patients—not those with kidney failure—drink ample fluids to help reduce kidney-stone formation. For patients with painful kidney stones or stones that are affecting urine flow, doctors may recommend a visit to a qualified medical professional who will remove them or break them up by a procedure called lithotripsy. In severe cases, the patient

QUESTIONS TO ASK YOUR DOCTOR

- What type of hyperoxaluria do I have?
- Is there a cure for hyperoxaluria?
- Is there a diet that will help reduce my symptoms?
- Are there foods I should avoid?
- What is the best treatment for my type of hyperoxaluria?
- Should I or my family members have genetic testing?

may require kidney dialysis. According to the Oxalosis and Hyperoxaluria Foundation, while dialysis can remove oxalate from the blood, it typically cannot keep pace with the very large amount of oxalate produced in patients with primary hyperoxaluria. For them, the only definitive treatment of kidney failure and oxalosis is transplantation.

There is no way to prevent hyperoxaluria in a given individual. It is an inherited disorder.

Adults who are carriers may wish to undergo genetic counseling before deciding to have children so in order to better understand the risks. Parents of children born with hyperoxaluria may want to have genetic testing to determine whether they are carriers of genetic mutations in the *AGXT* or *GRHPR* genes. The siblings of an affected child may also want to be tested. Brothers and sisters of a child with the disorder have a 25% chance of having the disorder themselves and a 50% chance of being a carrier for the disorder.

Prognosis

Some patients with hyperoxaluria experience kidney stones but no other health problems. Others, especially those with primary hyperoxaluria, have far more severe effects. According to the Oxalosis and Hyperoxaluria Foundation, about one-half of the individuals with primary hyperoxaluria experience kidney failure by age 15 and about 80% by age 30.

Hyperphenylalaninemia

Definition

Hyperphenylalaninemia (HPA) is elevated levels of phenylalanine in the blood. It is an inherited metabolic disorder caused by an inability to effectively break down or metabolize dietary phenylalanine that may lead to intellectual impairment if left untreated. This disorder is distinguished from phenylketonuria by lower levels of phenylalanine in the blood and increased tolerance of dietary phenylalanine.

Description

Hyperphenylalaninemia is broadly defined as an increased level of phenylalanine in the blood. However, there are two disorders that fall under this broad category: phenylketonuria (PKU) and mild hyperphenylalaninemia. These disorders are differentiated from one another by the level of phenylalanine present in the blood. Phenylalanine levels above 20 mg/dL indicate phenylketonuria. Levels between 2 and 20 mg/dL are considered mild hyperphenylalaninemia.

Elevated blood phenylalanine levels of more than 12 mg/dL cause damage to the nervous system, resulting in intellectual impairment or intellectual disability. A protein-restricted diet and supplementation with phenylalanine-free foods are used to decrease the blood phenylalanine levels of people with mild hyperphenylalaninemia.

Genetic profile

Mild hyperphenylalaninemia is a genetic disorder caused by mutations in the *PAH* gene, which provides the instructions for the enzyme phenylalanine hydroxylase.

KEY TERMS

Amino acids—Organic compounds that form the building blocks of protein. There are 20 types of amino acids (eight are “essential amino acids” that the body cannot make and that must be obtained from food).

Enzyme—A protein that catalyzes a biochemical reaction or change without changing its own structure or function.

Mutation—An inherited or *de novo* change in the DNA sequence of the genome.

Phenylalanine (Phe)—An essential amino acid that must be obtained from food since the human body cannot manufacture it.

Phenylalanine hydroxylase—The enzyme responsible for converting dietary phenylalanine to tyrosine. If phenylalanine hydroxylase is not working efficiently, phenylalanine levels in the blood increase.

Phenylketonuria (PKU)—An inherited inability to metabolize dietary phenylalanine, resulting in blood phenylalanine levels above 20 mg/dL. If left untreated, elevated blood phenylalanine levels can result in damage to the nervous system, including severe cognitive impairment, often referred to as intellectual disability.

Protein—Molecules made of amino acids that are found in various types of food such as meat and dairy products. People with mild hyperphenylalaninemia may have to limit the amount of protein that they eat.

This enzyme, located in the liver, is responsible for breaking down phenylalanine. Enzymes are molecules used by the body to digest food, and when they are not working properly, the result is metabolic disease.

Mild hyperphenylalaninemia is an inherited, autosomal recessive disorder. “Autosomal” simply means that the gene responsible for this disorder is not located on one of the sex chromosomes. “Recessive” refers to the fact that both of a person’s *PAH* genes are mutated. Genes come in pairs and provide the instructions for how an enzyme forms.

Since genes come in pairs, the parents of a person with mild hyperphenylalaninemia have one normal and one mutated *PAH* gene. When they have children, they pass on one of these genes. If their child inherits two

copies of the mutated gene (one from each parent), he or she will have hyperphenylalaninemia. When both parents are carriers of mutated *PAH* genes, they have a 25% chance that each of their children will have hyperphenylalaninemia.

Mutations of the *PAH* gene that cause mild hyperphenylalaninemia are not as harmful to enzyme function as the mutations that cause PKU. Different mutations affect enzyme activity differently. More serious mutations cause a greater loss of enzyme activity, leading to a greater buildup of phenylalanine in the blood. The mutations responsible for mild hyperphenylalaninemia cause less enzyme activity loss and less buildup of phenylalanine in the blood.

GTP-cyclohydrolase I deficiency (14q22.1-q22.2) is one cause of HPA. It is caused by a tetrahydrobiopterin deficiency that affects transmission of nerve impulses in the brain.

Demographics

Mild hyperphenylalaninemia occurs in 15 to 75 people per 1 million and is rarer than classic phenylketonuria, which occurs in about 1 in 15,000 births. It occurs in all races equally and affects both men and women.

Signs and symptoms

In the United States and Puerto Rico, all newborns are screened for HPA. If unscreened, mild to moderate intellectual deficits will be noted as the child grows up. A special diet until the late teens to mid-20s can prevent the detrimental effects of PKU buildup in the central nervous system and the subsequent damage. If left untreated, intellectual impairment, seizures, and dystonia (muscle weakness) can result.

Diagnosis

Tests

The diagnosis of hyperphenylalaninemia is usually made through a newborn screening test performed at birth. The United States and Puerto Rico have newborn screening programs, and the test is required by law. A blood sample is collected from the infant with a prick of the heel (heelstick), and the level of phenylalanine and other amino acids are quantitated using a technology called tandem mass spectrometry or MS/MS. If the initial newborn screening tests show an elevated phenylalanine level, then follow-up confirmatory blood tests are ordered to determine if the elevated phenylalanine level is due to phenylketonuria (PKU), mild hyperphenylalaninemia, or another reason. It is not uncommon for infants with

QUESTIONS TO ASK YOUR DOCTOR

- What is my baby's phenylalanine level?
- Does my baby need to be on a special diet?
- Can I still breastfeed my baby?

initially elevated phenylalanine levels on a newborn screening test to have normal follow-up tests.

If an infant's follow-up test indicates a persistently elevated phenylalanine level, further confirmatory testing will be done to determine if the infant has phenylketonuria or mild hyperphenylalaninemia. The diagnosis of mild hyperphenylalaninemia is made if the blood phenylalanine level is between 2 and 20 mg/dL on an unrestricted diet.

Treatment and management

Traditional

Dietary restriction of protein, which contains phenylalanine, is the main treatment for hyperphenylalaninemia. Mild hyperphenylalaninemia may or may not require treatment depending on the phenylalanine level. Individuals with phenylalanine levels greater than 2 mg/dL but less than 6 mg/dL do not generally require treatment. Dietary treatment is controversial in people with serum phenylalanine levels greater than 7 mg/dL but less than 11 mg/dL, with some studies showing a benefit while others do not. Dietary treatment is recommended in people with serum phenylalanine levels greater than 12 mg/dL. The treatment of mild hyperphenylalaninemia is usually handled by a team of medical professionals, including a geneticist and metabolic nutritionist.

Untreated mild hyperphenylalaninemia can lead to a decrease in IQ. Elevated serum levels of phenylalanine are directly related to IQ levels. The goal of dietary treatment is to keep serum phenylalanine levels below 10 mg/dL.

It is usually possible to breastfeed infants with mild hyperphenylalaninemia. The use of the artificial sweetener aspartame may be restricted, as phenylalanine is the primary component of this sweetener.

Drugs

The brand name drug Kuvan is a synthetic form of a cofactor for phenylalanine hydroxylase. This cofactor increases the efficiency of phenylalanine hydroxylase and

can decrease blood phenylalanine levels in some patients. It is used in conjunction with a phenylalanine-restricted diet. People with mild hyperphenylalaninemia may also use special foods and formula that are specially formulated and do not contain phenylalanine.

Prognosis

The prognosis for individuals with mild hyperphenylalaninemia is excellent. With early detection through newborn screening and dietary management when necessary, people affected with mild hyperphenylalaninemia are expected to have a normal life expectancy and normal intelligence quotient (IQ).

Women with blood phenylalanine levels above 6 mg/dL during pregnancy are at increased risk of having children with birth defects such as microcephaly or heart defects. Women with mild hyperphenylalaninemia should be seen in a metabolic center prior to pregnancy to aid in management of phenylalanine levels during pregnancy.

Hypochondrogenesis

Definition

Hypochondrogenesis is a lethal genetic skeletal dysplasia caused by a mutation in the *COL2A1* gene. This condition is characterized by a severe limb and trunk shortening with a disproportionately large head. Infants with this disorder usually die of respiratory failure soon after birth.

Description

Hypochondrogenesis is a rare form of skeletal dysplasia (or dwarfing syndrome) caused by mutations in the *COL2A1* gene. The *COL2A1* gene provides the instruction for the formation of collagen type II, which is a major building block of cartilage, a major component of bone. Because of these mutations, infants with hypochondrogenesis have defects in their bone formation that cause them to have severely shortened limbs (arms and legs) and a small chest with short ribs. Because infants with hypochondrogenesis have small chests and abnormal ribs, their lungs are underdeveloped, which leads to respiratory (breathing) difficulties at birth. In addition, the vertebrae or spinal bones in the neck and part of the sacrum (pelvis) do not harden, or ossify, properly. The face of an infant with hypochondrogenesis is flat and oval-shaped, with widely spaced eyes, a small chin, and, in some cases, an opening in the roof of the mouth called a cleft palate. Rarely, fetuses with hypochondrogenesis can develop a condition called hydrops fetalis in which excess fluid builds up in the abdomen and body before birth. One report has suggested that some infants with hypochondrogenesis may also have heart defects.

There are many causes for impaired growth or dwarfism, including hormone imbalances, metabolic problems, genetic disorders, and problems with bone growth. Hypochondrogenesis belongs to a class of dwarfism referred to as a chondrodystrophy or skeletal dysplasia and results from a problem with bone growth. All skeletal dysplasias are the result of a problem with bone formation or growth. There are more than 100 different types of skeletal dysplasias. Hypochondrogenesis is also sometimes referred to as a collagenopathy because the specific abnormality in hypochondrogenesis is a problem in the formation of collagen.

The collagenopathies are a group of disorders that affect connective tissue, the tissue that supports the body's joints and organs. Collagenopathies, as a group, are caused by defects in either type II or type IX collagen. Hypochondrogenesis is caused by a defect in the formation of type II collagen. Collagen is a complex protein molecule that provides structure, strength, and elasticity to connective tissue.

There are other skeletal dysplasias that have features very similar to hypochondrogenesis and are associated with mutations in the same gene. Consequently, hypochondrogenesis is considered by most specialists to belong to a spectrum, or continuum, of skeletal dysplasias that vary in severity. This spectrum includes achondrogenesis type II at the severe end and spondyloepiphyseal dysplasia congenita (SEDC) at the milder end. Infants with achondrogenesis type II have the same spinal changes as seen in hypochondrogenesis, but the condition is generally more severe and is invariably lethal. Infants with spondyloepiphyseal dysplasia congenita have the same findings as an infant with hypochondrogenesis, but their condition tends to be milder. Infants with SEDC can survive into adult life, but they generally have many complications due to their severe skeletal problems.

Genetic profile

Hypochondrogenesis is caused by a mutation, or change, in the *COL2A1* gene located on the long arm of chromosome 12 (12q13.11-q13.2). Hypochondrogenesis has autosomal dominant inheritance; however, there is usually no prior history of the condition in the family. In an autosomal dominant disorder, only one gene has to have a mutation for the person to have the disorder. All individuals have two *COL2A1* genes: one from their father and one from their mother. However, all infants with hypochondrogenesis are born to average-stature parents. The infant's hypochondrogenesis is the result of a *de novo*, or new, mutation. The occurrence of hypochondrogenesis is almost always due to a *de novo* mutation that typically occurs in one of the *type II collagen* genes from an average-sized parent. The cause of *de novo* mutations is unknown. Because infants with hypochondrogenesis do not survive to reproductive age, there is no risk of their passing on this mutated gene to the next generation. Because most *de novo* mutations occur sporadically, the recurrence risk is small.

Several different types of mutations in the *COL2A1* gene are responsible for hypochondrogenesis. These mutations may include small deletions, or missing pieces, of the *COL2A1* gene, missense mutations that lead to the substitution of one amino acid for another, and other changes that leave out important parts of the protein. All of these changes interfere with the formation of mature triple-stranded type II collagen molecules, which results in hypochondrogenesis by affecting tissues that are rich in type II collagen.

Demographics

Hypochondrogenesis occurs equally in males and females and is found with equal frequency in all races

and ethnic groups. There is no exact prevalence data for hypochondrogenesis, but collectively, collagenopathies are found in about 1 in 10,000 people. Because achondrogenesis and hypochondrogenesis can be difficult to tell apart, the incidence data reflect the incidence of both disorders. Hypochondrogenesis and achondrogenesis type II together occur in approximately 1 in 40,000–60,000 births. With the advent of DNA testing and the ability to make a more definitive diagnosis, it should soon be possible to have an incidence figure for hypochondrogenesis alone.

Signs and symptoms

Physical findings

Type II collagen is a major building block of the spine, cartilage, and vitreous protein in the eye. Defects in this collagen and the cartilage that it forms cause infants with hypochondrogenesis to have micromelia (extremely short limbs), a short trunk (or body) with shortened ribs, and a head that appears large. Their flat, oval-shaped faces have a characteristic appearance with wide-set eyes (hypertelorism), small chin, and, occasionally, a cleft palate or opening on the roof of the mouth. These infants may also have heart defects.

X-ray findings

Infants with hypochondrogenesis have very characteristic or unique x-ray findings. In order to understand what these findings are, it is important to know a little bit about how x-rays work. X-rays are a form of energy that is able to pass through some objects and not others. When x-rays pass through a body, more x-rays are absorbed by the denser parts (such as teeth and bone) than by softer tissues (such as muscles and digestive organs). X-rays create a negative image on the x-ray film. Soft tissues, such as blood, muscles, and digestive organs, appear darker or do not appear at all because the x-rays pass directly through the tissues onto the film. Bones and teeth appear brighter because fewer x-rays penetrate these structures and reach the film during exposure.

When looking at the x-ray of an infant with hypochondrogenesis, the observer can easily see abnormalities in the child's bones. Because the vertebrae are underdeveloped and have not hardened, they are quite difficult to see on an x-ray; normally, they should be easy to see. Those vertebrae that can be seen are usually abnormally shaped. The ribs appear very thin. In addition to vertebral and rib abnormalities, the bones of the pelvis and, in particular, the hip socket are abnormally shaped. Hip sockets are usually curved, but in hypochondrogenesis these bones are flattened and smaller than usual.

While the findings in hypochondrogenesis are distinctly abnormal, it is important to distinguish these findings from those seen in achondrogenesis type II and those seen in spondyloepiphyseal dysplasia congenita. The x-ray findings of achondrogenesis type II are more severe than those of hypochondrogenesis, and the findings of SEDc are generally milder than those seen in hypochondrogenesis.

Diagnosis

The diagnosis of hypochondrogenesis can be made prenatally by ultrasound or shortly after birth. A number of different tests, including x-rays, biopsies, and DNA testing, is used to confirm the diagnosis. Consultation with experts in the field of skeletal dysplasias may also be helpful.

The diagnosis of hypochondrogenesis can be made prenatally (during pregnancy), either by ultrasound (sonogram) or by prenatal DNA testing. Sonograms use sound waves to provide an image of a fetus. The structural abnormalities of hypochondrogenesis, including severely shortened limbs, shortened trunk with abnormal ribs, and unossified vertebral bones, can be observed during the second trimester of pregnancy. Because of overlapping features with other skeletal dysplasias, it can be very difficult to definitively diagnose hypochondrogenesis by sonogram. DNA testing can have a role in clarifying ambiguous ultrasound findings.

The neonatal diagnosis in infants is made by physical examination shortly after birth. Severe shortening of the limbs, a small trunk, abnormal facial features, and a cleft palate are often seen and raise the suspicion of the diagnosis of hypochondrogenesis. The diagnosis cannot be made by physical examination alone because hypochondrogenesis and numerous other skeletal dysplasias look very similar.

X-rays are often helpful in establishing the diagnosis of hypochondrogenesis. X-ray findings include underossified vertebra, abnormally thin ribs, and abnormally shaped hip bones. The x-ray findings of achondrogenesis type II are generally more severe, and the findings of SEDc are less severe.

Biopsies are the collection of tissue that can then be examined under a microscope. In hypochondrogenesis, a skin biopsy may be done to obtain skin cells for DNA analysis. Biopsies of the connective tissue may also be collected so that the collagen and other connective tissues can be examined microscopically.

DNA testing can be performed on a blood or skin sample. The presence of a mutation in the *COL2A1* gene would confirm the diagnosis of hypochondrogenesis. It is estimated that DNA testing will detect greater than

KEY TERMS

Achondrogenesis—A genetic disorder of skeletal development with three subtypes, one of which (achondrogenesis type II) is caused by mutations in the same gene as hypochondrogenesis.

Autosomal dominant—A pattern of genetic inheritance in which only one abnormal gene is needed to display the trait or disease.

Chondrodystrophy—A general term for any of several disorders of the skeleton caused by mutations that affect the normal development of cartilage.

Collagen—The main structural protein found in the various types of connective tissue in humans and other animals. It is found in skin, ligaments, tendons, cartilage, and the intervertebral disks in the spine. Disorders of collagen are called collagenopathies.

De novo mutation—A genetic mutation that is not inherited from either parent. The Latin phrase means “new.”

Dysplasia—A general term used to refer to abnormalities of growth or development.

Hydrops fetalis—The abnormal accumulation of fluid in the skin, body cavities, and placenta of an unborn baby.

Hypertelorism—Abnormally widely spaced eyes.

Micromelia—Abnormal shortness or smallness of the limbs.

Neonatologist—A pediatrician who specializes in the care of newborns, particularly sick or premature newborns.

Skeletal dysplasias—A group of syndromes consisting of abnormal prenatal bone development and growth.

Spondyloepiphyseal dysplasia congenita—A subtype of collagenopathy, types II and IX, with symptoms that are similar to but milder than those of hypochondrogenesis and achondrogenesis type II.

90% of mutations in the *COL2A1* gene. Because scientists have not yet found all of the mutations in this gene, the absence of a detectable mutation does not completely rule out the diagnosis. The *COL2A1* gene is a large gene with many possible mutations. Because of this complexity, the results of DNA testing may take four to six weeks.

Prenatal testing can also be done using DNA technology. A sample of tissue from a fetus is obtained by either chorionic villus sampling (CVS) or by amniocentesis. CVS is generally done between 10 and 12 weeks of pregnancy, and amniocentesis is done between 14 and 18 weeks of pregnancy. CVS involves removing a small amount of tissue from the developing placenta. The tissue in the placenta contains the same DNA as the fetus. Amniocentesis involves removing a small amount of fluid from around the fetus. This fluid contains some fetal skin cells from which DNA can be isolated. The fetal DNA is then tested to determine whether there are any mutations in the *COL2A1* gene. This test is not done in low-risk couples and may be available only if a specific mutation has already been characterized in a family. Molecular genetic testing for hypochondrogenesis was available in three genetic testing laboratories in the United States as of 2015.

Because hypochondrogenesis is such a rare disorder and has a great deal of overlap with other skeletal dysplasias, it can be very difficult to diagnose definitively. It can be helpful to consult with skeletal dysplasia experts who may suggest further specialized testing to help clarify the diagnosis.

Treatment and management

There is no cure or treatment for hypochondrogenesis. If the diagnosis is made prior to birth, the parents may wish to meet with a neonatologist to discuss management of the birth.

If hypochondrogenesis is detected during a pregnancy, patients have the option to terminate the pregnancy based upon the lethality of this condition. This is a very personal decision and should be made following serious counseling about the nature and outcome of this diagnosis.

Once the diagnosis has been firmly established, there is no need for resuscitation and ventilatory support for the infant given the established lethality of the condition. Infants should be provided with basic supportive care, including warmth, nourishment, and comfort.

If the diagnosis has not been confirmed prior to birth, resuscitation and ventilatory (breathing) support are appropriate to allow time for a thorough diagnostic evaluation. X-rays should be performed, and skin and connective and blood tissue should be collected.

The diagnosis of hypochondrogenesis is shocking for families. The bleak prognosis and lack of treatment can be devastating. Families should be reassured that there is nothing that they did or did not do that could have prevented the outcome. The family needs time to process the information about the diagnosis and should be

QUESTIONS TO ASK YOUR DOCTOR

- How common are mutations in the *COL2A1* gene?
- Are there steps that we should take to prepare for the poor prognosis of this disorder?
- Should other family members be tested for possible *de novo* mutations in the *COL2A1* gene?
- What research is being done to improve understanding of hypochondrogenesis and related disorders?

provided emotional support. The neonatal staff can aid in collecting reminders of the baby, including footprints, photographs, and locks of hair, that can help the family as they deal with the crisis. In addition to providing emotional support, it is equally important to make sure that the parents understand the genetic diagnosis and its implications for future pregnancies. They need to understand the sporadic nature of this diagnosis and that it is unlikely to recur in a future pregnancy. Because the interpretation of some of the test results are complicated, it is best that the family be referred to a genetics center for counseling following the diagnosis of hypochondrogenesis.

Prognosis

The prognosis for an infant with hypochondrogenesis is poor. Some infants are stillborn, and those that are born alive die shortly after birth due to respiratory failure. Survival can range from a few days to a few weeks. If an infant with suspected hypochondrogenesis does survive the newborn period, it is assumed that he or she actually has spondyloepiphyseal dysplasia congenita. In cases in which the diagnosis is ambiguous, DNA testing can help to confirm the diagnosis and may allow for a more accurate prognosis.

Hypochondroplasia

Definition

Hypochondroplasia is an autosomal dominant mutation that results in short stature with disproportionately short arms and legs but normal head size.

Description

Hypochondroplasia is a genetic form of short stature (dwarfism) due to a problem of bone growth and development. There are many causes for short stature, including hormone imbalances, metabolic problems, and problems with bone growth. Hypochondroplasia is a common form of short stature and belongs to a class of dwarfism referred to as a chondrodystrophy or skeletal dysplasia. All skeletal dysplasias are the result of a problem with bone formation or growth. There are over 300 different types of skeletal dysplasia.

Because the features of hypochondroplasia are so mild, the disorder may go undiagnosed. Although infants with hypochondroplasia may have low birth weight, hypochondroplasia is often not evident until between two and six years of age. In general, individuals with hypochondroplasia have disproportionate short stature with an

average height of 51–57 in. (130–145 cm). The degree of disproportion of the limbs to the body is variable.

Most individuals with hypochondroplasia have a normal IQ, although some studies suggest that up to 10% of individuals with hypochondroplasia may have mild intellectual disabilities or learning disabilities. This finding is controversial, and as of 2015, more studies were underway to verify it. The motor development of infants with hypochondroplasia is normal. In rare cases, individuals with hypochondroplasia may experience neurologic problems due to spinal cord compression. The spinal canal (which holds the spinal cord) can be smaller than normal in patients with hypochondroplasia.

Genetic profile

Hypochondroplasia is caused by a mutation, or change, in the fibroblast growth factor receptor 3 gene (*FGFR3*) located on the short arm of chromosome 4.

FGFR (fibroblast growth factor receptor) genes provide the instruction for the formation of a cell receptor. Every cell in the body has an outer layer called a cell membrane that serves as a filter. Substances are transported into and out of the cells by receptors located on the surface of the cell membrane. Every cell has hundreds of different types of receptors. The fibroblast growth factor receptors transport fibroblast growth factor into a cell. Fibroblast growth factors play a role in the normal growth and development of bones. When the receptors for fibroblast growth factor do not work properly, the cells do not receive enough fibroblast growth factor, and the result is abnormal growth and development of bones.

Approximately 70% of hypochondroplasia is caused by mutations in the *FGFR3* gene. The genes (or gene) responsible for the other 30% of cases are not known. The *FGFR3* gene consists of 2,520 bases. In a normal (nonmutated) gene, base number 1,620 codes for the amino acid asparagine. In most individuals with hypochondroplasia, a mutation changes the asparagine to the amino acid lysine. Two specific mutations account for approximately 70% of hypochondroplasia. These small substitutions change the amino acid that affects the protein structure. Both of these small substitutions cause a change in the *FGFR* that affects the function of this receptor.

The remaining 30% of patients diagnosed with hypochondroplasia do not show *FGFR3* gene mutations. It has not yet been made clear if these patients have a different gene abnormality, an unrecognized *FGFR3* gene mutation, or are normal variants. Another possibility is that

these individuals actually have another disorder in which short stature results.

Mutations in the *FGFR3* gene are inherited in an autosomal dominant manner. Individuals have two *FGFR3* genes—one from their father and one from their mother. In an autosomal dominant disorder, only one gene has to have a mutation for a person to have the disorder. An individual with hypochondroplasia has a 50% chance of passing on his or her changed (mutated) gene to offspring. An individual can inherit a mutated gene from one parent or the mutation can occur for the first time in the individual. Mutations that arise for the first time in affected individuals are called *de novo* mutations. The causes of mutations are not known.

Demographics

Because hypochondroplasia has such a wide range of variability, many people mildly affected with hypochondroplasia may never be diagnosed. Thus, the true incidence of hypochondroplasia is unknown. Experts believe that hypochondroplasia may be as common as achondroplasia, which occurs in 1 out of every 15,000 to 40,000 births. As of 2015, there were more than 200 diagnosed cases of hypochondroplasia worldwide.

Signs and symptoms

Individuals with hypochondroplasia have disproportionate short stature, limb abnormalities, and rhizomelic shortening of the limbs. Rhizomelic shortening of the limbs means that those segments of a limb closest to the body (the root of the limb) are more severely affected. In individuals with hypochondroplasia, the upper arms are shorter than the forearms and the upper leg (thigh) is shorter than the lower leg. In general, the upper limbs are more affected than the lower limbs in individuals with hypochondroplasia.

In addition to shortened limbs, individuals with hypochondroplasia have other characteristic limb differences such as a limited ability to rotate and extend their elbows. They can develop bowed legs, a finding that usually improves as they get older. Their hands and feet are short and broad, as are their fingers and toes. Their final adult height is usually 51–57 in. (130–145 cm). Their body habitus or shape is described as thick and stocky with a relatively long trunk. They may have lumbar lordosis (curved back), giving them a swayed back appearance.

Diagnosis

The diagnosis of hypochondroplasia can be extremely difficult to make for a number of reasons. There is no one physical feature or x-ray finding specific to hypochondroplasia, and there is a great deal of overlap between

KEY TERMS

Fibroblast growth factor receptor gene—A type of gene that codes for a cell membrane receptor involved in normal bone growth and development.

Rhizomelic—Disproportionate shortening of the upper part of a limb compared to the lower part of the limb.

individuals with hypochondroplasia and individuals in the general population. Many of the physical findings of hypochondroplasia (short stature, bowed legs, and a stocky build) are seen in individuals without hypochondroplasia. The same is true for the “typical” x-ray findings. All of the possible x-ray findings associated with hypochondroplasia can also be seen in unaffected individuals. There is no consensus on specific criteria necessary for diagnosis; however, it is usually made based on a combination of physical and x-ray findings and is rarely made in infants.

DNA testing for hypochondroplasia is complicated because testing only detects 70% of the mutations that cause hypochondroplasia. DNA testing can be performed on blood samples from children or adults. If an individual is suspected of having hypochondroplasia and a mutation is detected, then the diagnosis is confirmed. If a mutation is not detected, then the diagnosis of hypochondroplasia has neither been confirmed nor ruled out. This individual could be one of the 30% of individuals with hypochondroplasia due to unknown mutations, or they could have short stature due to another disorder.

Prenatal testing for hypochondroplasia can be performed using DNA technology. A sample of tissue from a fetus is obtained by either chorionic villus sampling (CVS) or by amniocentesis. CVS is generally done between 10 and 12 weeks of pregnancy, and amniocentesis is done between 16 and 18 weeks of pregnancy. CVS involves removing a small amount of tissue from the developing placenta. The tissue in the placenta contains the same DNA as the fetus. Amniocentesis involves removing a small amount of fluid from around the fetus. This fluid contains some fetal skin cells. DNA can be isolated from these skin cells. The fetal DNA is then tested to determine whether it contains either of the two mutations responsible for achondroplasia.

Prenatal DNA testing for hypochondroplasia is not routinely performed in low-risk pregnancies. This type of testing is generally limited to high-risk pregnancies, such as when one parent has hypochondroplasia. This testing can only be performed if the mutation causing hypochondroplasia in the parent has been identified.

Treatment and management

There is no cure for hypochondroplasia. Because of the wide range of variability of this condition, there is no consensus on the medical management of individuals with hypochondroplasia, either. Individuals with more severe cases are the only individuals likely to need medical management. The recommendations for the medical management of individuals with hypochondroplasia have been outlined by the American Academy of Pediatrics’ Committee on Genetics and should be used as a guide for the management of individuals with severe hypochondroplasia. The potential medical complications of hypochondroplasia range from mild to moderate. Early intervention may avert some of the long-term consequences of these complications.

As children with hypochondroplasia develop, certain conditions and behaviors should be monitored. Their height, weight, and head circumference should be measured regularly and plotted on growth curves developed for children with hypochondroplasia as a guide. Neurologic problems such as lethargy, abnormal reflexes, or loss of muscle control should be seen by a neurologist to make sure that they are not experiencing compression of their spinal cord. Compression of the spinal cord is rare in individuals with hypochondroplasia but can occur because of the abnormal size of their spinal canal.

Children with hypochondroplasia should be monitored for sleep apnea. Sleep apnea occurs when an individual stops breathing during sleep. This can occur for several reasons, including obstruction of the throat by the tonsils and adenoids, spinal cord compression, and obesity. Individuals with hypochondroplasia are more prone to sleep apnea because of the changes in their spinal canal and foramen magnum. Treatment for sleep apnea depends on the cause of the sleep apnea. Obstructive sleep apnea is treated by surgically removing the tonsils and adenoids. Weight management may also play a role in the treatment of sleep apnea.

The bowed legs of children with hypochondroplasia usually improve as they get older and rarely require surgical intervention. Children with hypochondroplasia can often have an increased risk for middle ear infections, which can be treated with oral antibiotics and the surgical placement of ear tubes.

Children with visible physical differences can have difficulties in school and socially. Support groups such as Little People of America can be a source of guidance on how to deal with these issues. It is important that children with hypochondroplasia not be limited in activities that pose no danger.

Two treatments have been used to try to increase the final adult height of individuals with hypochondroplasia—limb-lengthening and growth hormone therapy. There are

QUESTIONS TO ASK YOUR DOCTOR

- My son has been diagnosed with hypochondroplasia. What causes this disorder?
- Will my son “grow out” of this condition, or is some type of treatment needed? If so, what kinds of treatments are available?
- Will growth hormone be useful in helping my son to grow normally?
- What long-term physical and mental problems is my son likely to experience as a result of this genetic disorder?

risks and benefits to both treatments and they are still considered experimental.

Limb-lengthening involves surgically attaching external rods to the long bones in the arms and legs. These rods run parallel to the bone on the outside of the body. Over a period of 18–24 months, the tension on these rods is increased, which results in the lengthening of the underlying bone. This procedure is long, costly, and has potential complications such as pain, infections, and nerve problems. Limb-lengthening can increase overall height by 12–14 in. (30.5–35.6 cm). This is an elective surgery and individuals must decide for themselves whether it would be of benefit to them. The optimal age to perform this surgery is not known.

Growth hormone therapy has been used to treat some children with hypochondroplasia. Originally, there was doubt about the effectiveness of this treatment because children with hypochondroplasia are not growth-hormone deficient. Studies have shown mixed results. Some children with hypochondroplasia show improvement in their growth rate, and others do not. It is too early to say how effective this treatment is because the children involved in this study are still growing and have not reached their final adult height.

Prognosis

The prognosis for most people with hypochondroplasia is very good. In general, they have minimal medical problems, normal IQ, and most achieve success and have a long life, regardless of their stature. The most serious medical barriers to an excellent prognosis are the neurologic complications that very rarely arise in hypochondroplasia, including mild intellectual disability and spinal cord compression.

Successful social adaptation plays an important role in the ultimate success and happiness of an individual with hypochondroplasia. It is very important that the career and life choices of individuals with hypochondroplasia not be limited by preconceived ideas about their abilities.

Kathleen Fergus, MS

Hypophosphatasia

Definition

Hypophosphatasia is an inherited bone disease with highly variable clinical symptoms ranging from prenatal death to a severe lack of bone mineralization to early loss of teeth in adulthood. Hypophosphatasia is caused by a mutation in the *ALPL* gene that provides instructions for producing an enzyme called tissue-nonspecific alkaline

phosphatase (TNSALP) that is required for the proper mineralization (hardening) of bones.

Description

Hypophosphatasia means “low phosphatase.” Phosphatase is an enzyme that removes phosphate molecules (PO_4^{3-}) from other molecules in the body and supplies phosphate to bone. The term “hypophosphatasia” was first used in 1948 by a Canadian pediatrician, J. C. Rathbun, to describe an infant who died of what appeared to be severe rickets, weight loss, and seizures. Rickets is caused by vitamin D deficiency, which interferes with the absorption and utilization of calcium and phosphorus, which are required for proper bone growth and development; however, this child had very low levels of alkaline phosphatase. In 1953, the clinical features of hypophosphatasia were expanded to include not only abnormal mineralization of bone but also premature loss of the permanent teeth in adulthood. Hypophosphatasia is now classified into six types, based on the severity of the disease and the age at which symptoms first appear:

- perinatal lethal hypophosphatasia
- perinatal benign hypophosphatasia
- infantile hypophosphatasia
- childhood hypophosphatasia
- adult hypophosphatasia
- odontohypophosphatasia

Alkaline phosphatase (ALP) is an enzyme that occurs in most all plants and animals. There are at least four different genes that encode different forms of ALP in humans. Hypophosphatasia is caused by a deficiency of TNSALP, the form of ALP that is particularly abundant in the liver, bones, and kidneys. TNSALP is important for mineralization of the bones of the skeleton, as well as the teeth. Thus, abnormalities in either the production or function of this enzyme have a direct effect on the formation and strength of bones and teeth. Low levels of active TNSALP result in the abnormal buildup in the body of several other substances that are normally processed by the enzyme. In particular, it is believed that the buildup of inorganic pyrophosphate results in the defective mineralization of the bones and teeth.

Genetic profile

The first report of siblings affected by hypophosphatasia was published in 1950, providing supportive evidence that this was an inherited disorder rather than an acquired disease. The gene for TNSALP is located near the tip of the short arm (p) of chromosome 1 at 1p36.12.

The most severe forms of hypophosphatasia—perinatal lethal and infantile—are inherited as an

autosomal recessive condition. This means that an affected infant must inherit two copies of a mutated *ALPL* gene, one copy from each parent. Each child of parents who both carry a mutated *ALPL* gene has a 25% (one in four) chance of being affected by perinatal lethal or infantile hypophosphatasia and a 50% chance of inheriting one mutated gene.

The milder forms of hypophosphatasia, especially the adult form and odontohypophosphatasia, are inherited as either autosomal recessive or autosomal dominant conditions, depending on the specific mutation in the *ALPL* gene. Individuals who inherit a single autosomal recessive *ALPL* gene mutation have low TNSALP enzyme activity but either have no symptoms or milder symptoms, depending on the specific mutation. There also have been reports of *de novo* autosomal recessive *ALPL* mutations that occurred in the egg or sperm cell or during early embryonic development; in such cases, neither parent carried a mutated *ALPL* gene. Individuals who inherit a single autosomal dominant *ALPL* gene have hypophosphatasia, and each of their children has a 50% risk of inheriting the pathogenic *ALPL* gene.

More than 200 different *ALPL* mutations have been associated with hypophosphatasia, and the severity of the disorder depends on the specific mutation. Mutations that do not completely eliminate the activity of TNSALP cause milder and/or later-onset forms of the disorder. Thus, even some children who inherit two mutated *ALPL* genes have only mild symptoms or no symptoms at all, depending on the specific mutations.

Demographics

The prevalence of autosomal recessive perinatal lethal and infantile hypophosphatasia in Ontario, Canada, has been estimated at 1 in 100,000. This would make the frequency of pathogenic *ALPL* mutation carriers about 1 in 150 individuals. Hypophosphatasia is especially common among Mennonite families in Manitoba, Canada, where marriages between related individuals are not unusual. The frequency of the perinatal lethal form in this population is approximately 1 in 2,500, with a corresponding carrier frequency of 1 in 25. The number of different *ALPL* mutations identified in this group is smaller than in the general population. It is difficult to estimate the frequency of milder childhood and adult hypophosphatasia and odontohypophosphatasia, but these forms are probably more common.

Hypophosphatasia has not been reported from Africa outside of North Africa. The disorder is very rare among African Americans.

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted either through the mother's vagina or abdominal wall, and a sample of cells is collected from around the fetus. These cells are then tested for chromosome abnormalities or other genetic diseases.

Enzyme—A protein that catalyzes a biochemical reaction or change without changing its own structure or function.

Rachitic—Pertaining to, or affected by, rickets. Examples of rachitic deformities include curved long bones with prominent ends, a prominent middle chest wall, or bony nodules at the inner ends of the ribs.

Signs and symptoms

The major symptom of hypophosphatasia is generalized impairment of skeletal mineralization, but signs and symptoms vary greatly depending on the specific ALPL mutation(s) and levels of active TNSALP. Although signs and symptoms within affected families tend to be similar, variations are observed even within families. Even some individuals with low levels of TNSALP have no signs or symptoms of the disorder.

Perinatal hypophosphatasia

Lethal perinatal hypophosphatasia is often diagnosed prenatally. The limbs are typically shortened and abnormal. Bone fractures may be present. An excessive amount of amniotic fluid (polyhydramnios) is common. Many affected infants die prior to delivery or are stillborn. Those who survive are often irritable, have a high-pitched cry, and fail to gain weight. Respiratory failure is a common cause of death, usually due to deformities of the chest and associated underdevelopment of the lungs. In contrast, benign perinatal hypophosphatasia may cause prenatal

skeletal abnormalities that eventually resolve into a milder childhood or adult form.

Infantile hypophosphatasia

Many infants with this form of the disease appear normal at birth and initially develop normally. However, difficulties such as poor feeding, slow weight gain, and soft, deformed bones begin before six months of age. Bone abnormalities of the chest, as well as an increased susceptibility to fractures, make affected infants more susceptible to pneumonia. Over 50% of affected children die during infancy, usually from severe respiratory failure. Infants who survive often have episodes of recurrent vomiting and abnormal kidney function due to excess loss of calcium from bone. Additionally, they may develop a misshapen head due to early closure of bones of the skull. However, spontaneous overall improvement sometimes occurs.

Childhood hypophosphatasia

The most common clinical feature in this form of hypophosphatasia is loss of the primary (deciduous) teeth before the age of five. This premature loss is directly related to abnormal dental cementum, the bony layer that normally establishes the connections of the teeth to the jaw. Cementum is frequently completely missing, underdeveloped, or abnormal. Symptoms of more severe cases include short stature, skeletal deformities, and bone pain and fractures.

Adult hypophosphatasia

Although affected individuals are usually diagnosed in adulthood, careful review of medical histories often reveals childhood skeletal abnormalities and/or early loss of the primary teeth, followed by relatively good health during adolescence and young adulthood. Dental and skeletal difficulties occur gradually. Age at symptom onset and symptom severity vary. Early loss of the permanent teeth is common. Other common symptoms include osteomalacia (a softening of bones similar to rickets in children), bone fractures and deformities, and chronic foot pain due to recurrent, poorly healing stress fractures. Affected adults may experience pain in the thighs and hips from zones of decalcification (pseudo-fractures). Some older adults diagnosed with osteoporosis may actually have a mild form of hypophosphatasia.

Odontohypophosphatasia

Dental disease in children or adults is the only clinical abnormality associated with this form.

Diagnosis

Prenatal diagnosis of perinatal hypophosphatasia is usually apparent on ultrasound by midpregnancy. Fetal x-rays may confirm a diagnosis. ALP activity may be measured in cultured cells obtained by chorionic villus sampling (CVS) or amniocentesis; however, it can be difficult to directly test for TNSALP. Genetic tests are available for prenatal diagnosis, especially if the family mutation(s) has been identified.

Diagnosis of hypophosphatasia after birth is based on a combination of a physical examination, x-rays, and biochemical studies. X-rays can be particularly helpful in differentiating between the more severe forms of hypophosphatasia (perinatal, infantile) and other inherited bone diseases. In the perinatal form, the skeleton generally appears severely undermineralized and occasionally is absent. Bone fractures may be present. X-ray findings for the infantile form are similar to those seen in the perinatal form but are usually much less severe.

Blood serum is tested for low levels of alkaline phosphatase activity, which primarily represents TNSALP activity. Substances such as inorganic pyrophosphate, which are normally acted upon by TNSALP, accumulate in the blood and urine and can be measured. Genetic testing can also be used for diagnosis.

Treatment and management

Children with hypophosphatasia are treated with repeated infusions of TNSALP directed to bone. As of 2015, clinical trials of this treatment were underway in adults.

Management of hypophosphatasia is directed at preventing or treating disease-related complications. Physical therapy and orthopedic management are important for preventing and treating bone complications such as fractures. Expert dental care is very important. Young children with the infantile form should be monitored carefully for increased pressure within the skull from early fusion of the bones.

Prognosis

The prognosis for each type of hypophosphatasia depends on the age of onset and severity. In general, the earlier the diagnosis, the more severe the skeletal abnormalities. Mortality from lethal perinatal or infantile hypophosphatasia ranges up to 50% in the first year of life. However, infants with benign perinatal disease may spontaneously improve. Symptoms of childhood disease may improve during adolescence but occasionally reappear in adulthood. Adult-onset hypophosphatasia is associated with ongoing orthopedic problems. Women, in particular, may suffer increased bone loss and fractures after menopause.

Hypophosphatemia

Definition

Hypophosphatemia is a group of inherited disorders in which there is abnormally low levels of phosphate in the blood, leading to softening of the bones. This condition can result in rickets, a childhood disease in which soft and weak bones can lead to bone deformities. While there is no cure, treatment can prevent the bone changes and allow proper growth of bones.

Description

Bone is one of the strongest tissues of the human body. As the main component of the adult skeleton, it provides support for movement, protects the brain and organs

KEY TERMS

Hydroxyapatite—A complex phosphate of calcium $\text{Ca}_5(\text{PO}_4)_3\text{OH}$ that occurs as a mineral and is the chief structural element of vertebrate bone.

Hypophosphatemia—A decrease in the blood circulation of phosphate.

Rickets—A childhood disease in which soft and weak bones can lead to the development of bone deformities.

of the chest from injury, and contains the bone marrow, where blood cells are formed. Bone is made up of several components, including a substance called hydroxyapatite. Hydroxyapatite is made of calcium and phosphate and is partially responsible for the strength of bone.

Because of the importance of hydroxyapatite, the strength of bone is dependent on the proper levels of calcium and phosphate within the body. A lack of calcium or phosphate in the diet or a failure in maintaining proper levels of calcium or phosphate in the blood can lead to abnormalities of bone growth. Another factor required for proper development of bone is vitamin D. Vitamin D is either obtained through foods in the diet or is made by the body in response to sunlight exposure. Vitamin D is converted to another substance within the body called calcitriol. Calcitriol promotes bone development by helping to absorb calcium and phosphate from the diet and by preventing the loss of calcium and phosphate in the urine.

Hypophosphatemia is a group of inherited disorders in which there is abnormally low phosphate levels in the blood because large amounts of phosphate exit the body through the urine. In some forms of the disease there may be problems in the conversion of vitamin D to calcitriol. Research suggests that inherited hypophosphatemia syndromes result from an abnormality in the way the kidney handles phosphate. Normally, the kidney prevents phosphate from leaving the body in the urine, but in hypophosphatemia, an abnormality in the way the kidney handles phosphate leads to large losses of phosphate in the urine. This results in abnormally low levels of phosphate in the blood, leading to poor hydroxyapatite formation and soft bones. Insufficient levels of phosphate for bone formation results in rickets, a childhood condition in which there is abnormal bone development, growth, and repair (when this occurs in adults, it is called osteomalacia). Inherited hypophosphatemia was first described by R. W. Winters in 1958 and has been referred to in the past as vitamin D-resistant rickets or familial hypophosphatemic rickets.

Genetic profile

Hypophosphatemia is a group of conditions that can be inherited or passed on in a family. The different types of hypophosphatemia have different causes, patterns of inheritance, and symptoms.

The most common and widely studied form of hypophosphatemia is hereditary hypophosphatemia type I, also known as X-linked hypophosphatemia (XLH). The abnormality in XLH is in a gene called *PHEX*. It is not known precisely how this gene affects phosphate handling by the kidney. Changes in other genes have been shown to cause hypophosphatemia, but the mechanism is similarly unclear. While most occurrences of hypophosphatemia are passed from parent to child, there are several examples of new genetic changes arising in a child with no relatives with hypophosphatemia.

There are different patterns of inheritance in different forms of hypophosphatemia, including autosomal dominant inheritance and X-linked dominant inheritance. In autosomal dominant inheritance, only one abnormal gene is needed to display the disease, and the chance of passing the gene to offspring is 50%.

X-linked dominant inheritance is similar to autosomal dominant inheritance in that only one abnormal gene is needed to display the disease. However, in X-linked dominant inheritance, the genetic abnormality is located on the X chromosome. Females have two X chromosomes, whereas males only have one X chromosome. Females have a 50% chance of passing the abnormal gene on to either a son or a daughter, as the mother always contributes one X chromosome to a child. On the other hand, males with the abnormal X chromosome always pass the abnormal gene to a daughter (the father will contribute the abnormal X chromosome) but never to a son (the father will contribute a normal Y chromosome, and not the abnormal X chromosome).

Demographics

Hypophosphatemia has been estimated to be present in between 1 in 10,000 and 1 in 100,000 people, but 1 in 20,000 people is the most widely quoted figure. It is not known whether this disease is present equally among different geographical areas and ethnic groups. The first reports of the condition found hypophosphatemia in a Bedouin (nomadic Arab) tribe.

Signs and symptoms

Major symptoms of hypophosphatemia include poor growth, bone pain, abnormally bowed legs, weakness, tooth abscesses, and sometimes listlessness and irritability in infants and young children. Although the disease affects

QUESTIONS TO ASK YOUR DOCTOR

- Are there any dietary restriction/additions or supplements I should take to help support my bones?
- Are there any adverse side effects of the pharmaceuticals used to treat this condition?
- Can my future children be screened for this disorder, and what are the chances they will inherit it?

all bones, the legs are more severely affected than the arms, ribs, or pelvis. The bowed legs are often noted by 12 months of age, and the altered growth increases in severity as the child grows older. Because of poor hydroxyapatite formation, people may experience fractures and subsequent abnormal healing, further contributing to growth abnormalities. As a result of poor bone development and poor healing, people with hypophosphatemia often have short stature and may have a waddling walk. Other, less common manifestations of hypophosphatemia include high blood pressure and hearing loss or deafness.

While most symptoms are the same in the different types of hypophosphatemia, there may be small changes in the severity and age at which a person will experience the symptoms.

Diagnosis

If there is no family history of hypophosphatemia, diagnosis is usually guided by physical exam and bloodwork. Obvious bowed-leg deformities will lead to x-rays of the legs and knees, which show characteristic bone abnormalities. Other studies of bone strength using radioactive tracer materials can be used, or a bone biopsy (surgical excision of a small portion of bone for inspection with a microscope) can be performed to confirm that there is less hydroxyapatite than normal.

Laboratory tests aid in determining the cause of poor bone growth and rickets. In XLH, the serum phosphorus is low and the levels of serum calcium and calcitriol are low or sometimes normal. Urine levels of phosphate are high, indicating that phosphate is being lost in the urine and that the kidney is not reabsorbing the phosphate properly. Another laboratory finding in XLH is the presence of increased alkaline phosphatase, an enzyme that breaks down bone. However, alkaline phosphatase is often elevated in growing children compared to normal adult values. Other forms of hypophosphatemia may have

other variations in laboratory findings, including normal calcitriol levels or high levels of calcium in the urine and can be used to distinguish between the different types of hypophosphatemia.

Treatment and management

There is no cure, but medical and surgical treatment can greatly improve the outcome of people with hypophosphatemia. Goals of treatment include improvement in growth; reduction in severity of bone disease, bowed legs, and activity limitations; and minimization of the complications that may develop from the treatment itself.

Medical treatment is directed toward increasing the blood phosphate levels by using phosphate salts and calcitriol, both given by mouth. However, phosphate may have to be given five times a day because it is rapidly lost in the urine, and it often causes diarrhea. Despite these drawbacks, the response to the medications is very good, and bowed legs may straighten over several years of growth. Scientific studies are also being performed to determine if growth hormone can help in achieving normal growth and height development.

Healthcare providers are able to monitor the person's ability to take the medication by checking the phosphate levels in the urine and the blood. It is recommended that these tests be performed in small children every three months to determine if they are receiving adequate amounts of phosphate. Later, the monitoring can be decreased to every four to six months. It is also recommended that childhood x-rays of the knee be performed every one to two years to see whether medication changes are needed.

Some problems may result from the medications used to treat hypophosphatemia. High levels of calcium can build up in the bloodstream, causing problems with the kidneys and the parathyroid (a gland in the neck). Because of these problems, routine calcium measurements and kidney ultrasound studies should be performed to determine if additional medications should be added or changes in medications should be made.

Treatment with medication is sometimes not enough to reverse the bone abnormalities. In cases such as these, surgery can be performed to reshape or even lengthen the bones.

Prognosis

With early diagnosis and treatment, the prognosis for people with hypophosphatemia is excellent. Adult heights of 67 in. (170 cm) may be achievable, compared to 51–65 in. (130–165 cm) without treatment. While some degree of abnormal bone growth may always be

detectable, people with hypophosphatemia generally have normal lifespans.

Hypospadias and epispadias

Definition

Hypospadias is a congenital defect, primarily of males, in which the urethra opens on the underside (ventrum) of the penis. The corresponding defect in females is an opening of the urethra into the vagina and is rare.

Epispadias (also called bladder exstrophy) is a congenital defect of males in which the urethra opens on the upper surface (dorsum) of the penis. The corresponding defect in females is a fissure in the upper wall of the urethra and is quite rare.

Description

In a male, the external opening of the urinary tract (external meatus) is normally located at the tip of the

penis. In a female, it is normally located between the clitoris and the vaginal opening.

In males with hypospadias, the urethra opens on the inferior surface or underside of the penis. In females with hypospadias, the urethra opens into the cavity of the vagina.

In males with epispadias, the urethra opens on the superior surface or upper side of the penis. In females with epispadias, there is a crack or fissure in the wall of the urethra and out of the body through an opening in the skin above the clitoris.

During the embryological development of males, a groove of tissue folds inward and then fuses to form a tube that becomes the urethra. Hypospadias occurs when the tube does not form or does not fuse completely. Epispadias is due to a defect in the tissue that folds inward to form the urethra.

During the development of a female, similar processes occur to form the urethra. The problem is usually insufficient length of the tube that becomes the urethra. As a result, the urethra opens in an abnormal location, resulting in a hypospadias. Occasionally, fissures form in the bladder. These may extend to the surface of the abdomen and fuse with the adjacent skin. This is most often identified as a defect in the bladder although it is technically an epispadias.

Hypospadias in males generally occur alone. Female hypospadias may be associated with abnormalities of the genital tract, since the urinary and genital tracts are formed in the same embryonic process.

Because it represents incomplete development of the penis, some experts think that insufficient male hormone may be responsible for hypospadias.

Genetic profile

Hypospadias and epispadias are congenital defects of the urinary tract. This means that they occur during intra-uterine development. There is no genetic basis for the defects. Some hypospadias have been linked to manmade chemicals, but specific causes for most hypospadias are not known. This means that blood relatives do not have increased chances of developing them.

Demographics

In males, the incidence of hypospadias is approximately 1 per 250 to 300 live births. Epispadias is much less common, having an incidence of about 1 per 100,000 live male births.

In females, hypospadias is much less common than in males. It appears about once in every 500,000 live

KEY TERMS

Bladder—The organ that stores urine after it flows out of the kidneys and through the ureters.

Circumcision—The surgical removal of the foreskin of the penis.

Continence—Normal function of the urinary bladder and urethra, allowing fluid flow during urination and completely stopping flow at other times.

External meatus—The external opening through which urine and seminal fluid (in males only) leave the body.

Genital tract—The organs involved in reproduction. In a male, they include the penis, testicles, prostate, and various tubular structures to transport seminal fluid and sperm. In a female, they include the clitoris, vagina, cervix, uterus, fallopian tubes, and ovaries.

Urethra—The tubular portion of the urinary tract connecting the bladder and external meatus through which urine passes. In males, seminal fluid and sperm also pass through the urethra.

female births. Epispadias is even rarer. Reliable estimates of the prevalence of epispadias in females are not available. Epispadias in females is often diagnosed and recorded as a bladder anomaly.

Signs and symptoms

Hypospadias is usually not associated with other defects of the penis or urethra. In males, it can occur at any site along the underside of the penis. In females, the urethra exits the body in an abnormal location. This is usually due to inadequate length of the urethra.

Epispadias is associated with bladder abnormalities. In females, the front wall of the bladder does not fuse or close. The bladder fissure may extend to the external abdominal wall. In such a rare case, the front of the pelvis is also widely separated. In males, the bladder fissure extends into the urethra and simply becomes an opening somewhere along the upper surface of the penis.

Hypospadias is associated with difficulty in assigning gender to babies. This occurs when gender is not obvious at birth because of deformities in the sex organs.

Diagnosis

Male external urinary tract defects are discovered at birth during the first detailed examination of the newborn.

Female urethral defects may not be discovered for some time due to the difficulty in viewing the infant vagina.

Treatment and management

Surgery is the treatment of choice for both hypospadias and epispadias. All surgical repairs should be undertaken early and completed without delay. This minimizes psychological trauma.

In males with hypospadias, one surgery is usually sufficient to repair the defect. With more complicated hypospadias (more than one abnormally situated urethral opening), multiple surgeries may be required. In females with hypospadias, surgical repair is technically more complicated but can usually be completed in a brief interval of time.

Repairing an epispadias is more difficult. In males, this may involve other structures in the penis. Males should not be circumcised since the foreskin is often needed for the repair. Unfortunately, choices may be required that affect the ability to inseminate a female partner. Reproduction requires that the urethral meatus be close to the tip of the penis. Cosmetic appearance and urinary continence are usually the primary goals. Surgery for these defects is successful 70%–80% of the time. Modern treatment of complete male epispadias allows for an excellent genital appearance and achievement of urinary continence.

In females, repair of epispadias may require multiple surgical procedures. Urinary continence and cosmetic appearance are the usual primary considerations. Urinary continence is usually achieved, although cosmetic appearance may be somewhat compromised. Fertility is not usually affected. Repair rates that are similar or better than those for males can usually be achieved for females.

Hypospadias in both males and females is more of a nuisance and hindrance to reproduction than a threat to health. If surgery is not an option, the condition may be allowed to persist. This usually leads to an increased risk of infections in the lower urinary tract.

Prognosis

With adequate surgical repair, most males with simple hypospadias can lead normal lives with a penis that appears and functions in a normal manner. This includes fathering children. Females with simple hypospadias also have normal lives, including conceiving and bearing children.

The prognosis for epispadias depends on the extent of the defect. Most males with relatively minor epispadias lead normal lives, including fathering children. As the extent of the defect increases, surgical reconstruction is

QUESTIONS TO ASK YOUR DOCTOR

- Will my child be able to urinate normally?
- Will this condition lead to any other problems?
- How visible will the scars of the repair surgery be?

generally acceptable. However, many of these men are unable to conceive children. Most epispadias in females can be surgically repaired. The chances of residual disfigurement increase as the extent of the epispadias increases. Fertility in females is not generally affected by epispadias.

Ichthyosis

Definition

Derived from the Greek word meaning fish disease, ichthyosis is a congenital (present at birth) dermatological (skin) disease that is characterized by thick, scaly skin.

Description

The ichthyoses are a group of genetic skin diseases caused by an abnormality in skin growth that results in drying and scaling. It may occur as a symptom of a syndrome or as an individual skin condition. There are at least 20 types of ichthyosis. Ichthyosis can be more or less severe, sometimes accumulating thick scales and cracks that are painful and bleed. Ichthyosis is not contagious because it is inherited.

Genetic profile

Ichthyoses have been associated with mutations in many genes including *ABCA12*, *ABHD5*, *ALDH3A2*, *ALOX12B*, *ALOXE3*, *AP1S1*, *BRAF*, *CARD14*, *CLDN1*, *CSTA*, *CYP4F22*, *ERCC2*, *ERCC3*, *FLG*, *GJB2*, *GTF2H5*, *KRAS*, *KRT1*, *KRT10*, *LIPN*, *MAP2K1*, *MAP2K2*, *MBTPS2*, *MPLKIP*, *NIPAL4*, *NSDHL*, *PNPLA1*, *PNPLA2*, *POMP*, *SPINK5*, *SLC27A4*, *STS*, *SUMF1*, and *TGM1*. These genes are involved in skin production and maintenance.

Depending on the specific type of ichthyosis, the inheritance can be autosomal recessive, autosomal dominant, X-linked recessive, X-linked dominant, or sporadic. Autosomal recessive means that the altered gene for the disease or trait is located on one of the first 22 pairs of chromosomes, which are also called “autosomes.” Males

and females are equally likely to have an autosomal recessive disease or trait. Recessive means that two copies of the altered gene are necessary to express the condition. Therefore, a child inherits one copy of the altered gene from each parent, who are called carriers (because they have only one copy of the altered gene). Since carriers do not express the altered gene, parents usually do not know they carry the altered gene that causes ichthyosis until they have an affected child. Carrier parents have a one-in-four chance (or 25%) with each pregnancy to have a child with ichthyosis.

Autosomal dominant inheritance also means that both males and females are equally likely to have the disease but only one copy of the altered gene is necessary to have the condition. An individual with ichthyosis has a 50% chance of passing the condition to his or her child.

The last pair of human chromosomes, either two X (female) or one X and one Y (male) determines gender. X-linked means the altered gene causing the disease or trait is located on the X chromosome. Females have two X chromosomes while males have one X chromosome. The term “recessive” usually infers that two copies of a gene—one on each of the chromosome pair—are necessary to cause a disease or express a particular trait. X-linked recessive diseases are most often seen in males, however, because they have a single X chromosome and no “back-up.” So, if a male inherits a particular gene on the X, he expresses the altered gene, even though he has only a single copy of it. Females, on the other hand, have two X chromosomes and therefore can carry a gene on one of their X chromosomes yet not express any symptoms. (Their second X, or “back-up,” functions normally). Usually a mother carries the altered gene for X-linked recessive ichthyosis unknowingly and has a 50% chance with each pregnancy to transmit the altered gene. If the child is a male, he will have ichthyosis. If the child is a female, she will be a carrier for ichthyosis like her mother.

X-linked dominant inheritance means that only one gene from the X chromosome is necessary to produce

Ichthyosis is characterized by dry, scaly skin. (MedicImage/Alamy)

the condition. Mothers with the altered gene are affected and have a 50% chance to pass the condition to any child, who will also have ichthyosis. In some cases, X-linked dominant inheritance is lethal in males, which means that male fetuses with X-linked dominant ichthyosis are miscarried. This is true for a rare disorder called Conradi-Hunerman, in which ichthyosis is just one feature.

New mutations—alterations in the DNA of a gene—can cause disease. In these cases, neither parent has the disease-causing mutation. This may occur because the mutation in the gene happened for the first time only in the egg or sperm for that particular pregnancy. New mutations are thought to happen by chance and are therefore referred to as “sporadic,” meaning that they occur occasionally and are not predictable.

Demographics

The most common form of ichthyosis is called ichthyosis vulgaris (*vulgar* is Latin for common). It occurs in approximately 1 person in every 250 and is inherited in an autosomal dominant manner. The rarest types of ichthyosis occur in fewer than 1 person in 1 million and are inherited in an autosomal recessive

manner. Ichthyosis occurs regardless of the part of the world the child is from or the ethnic background of the parents.

Signs and symptoms

The skin is made up of several layers supported underneath by a layer of fat that is thicker or thinner depending on location. The lower layers contain blood vessels, the middle layers contain actively growing cells, and the upper layer consists of dead cells that serve as a barrier to the outside world. This barrier is nearly waterproof and highly resistant to infection. Scattered throughout the middle layers are hair follicles, oil and sweat glands, and nerve endings. The upper layer is constantly flaking off and being replaced from beneath by new tissue. In ichthyosis, the skin’s natural shedding process is slowed or inhibited, and in some types, skin cells are produced too rapidly.

The abnormality in skin growth and hydration of ichthyosis may present with symptoms at birth or in early childhood. Ichthyosis can itch relentlessly leading to complications caused by scratching such as lichen simplex (dermatitis characterized by raw patches of skin).

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman’s abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Amniotic fluid—The fluid that surrounds a developing baby during pregnancy.

Autosomal dominant—A pattern of genetic inheritance where only one abnormal gene is needed to display the trait or disease.

Autosomal recessive—A pattern of genetic inheritance where two abnormal genes are needed to display the trait or disease.

Dermatologist—A physician who specializes in disorders of the skin.

Emollient—Petroleum- or lanolin-based skin lubricants.

Keratin—A tough, non-water-soluble protein found in the nails, hair, and the outermost layer of skin. Human hair is made up largely of keratin.

Keratinocytes—Skin cells.

Keratolytic—An agent that dissolves or breaks down the outer layer of skin (keratins).

Retinoids—A derivative of synthetic vitamin A.

Sporadic—Isolated or appearing occasionally with no apparent pattern.

X-linked dominant inheritance—The inheritance of a trait by the presence of a single gene on the X chromosome in a male or female, passed from an affected female who has the gene on one of her X chromosomes.

X-linked recessive inheritance—The inheritance of a trait by the presence of a single gene on the X chromosome in a male, passed from a female who has the gene on one of her X chromosomes. She is referred to as an unaffected carrier.

Both cracked skin and itching may cause infection, discomfort, and necessitate additional treatment.

Diagnosis

A dermatologist will often make the diagnosis of ichthyosis based on a clinical exam. However, a skin

biopsy or DNA study (from a small blood sample) is necessary to confirm the diagnosis. A complete physical exam may be performed to check for additional medical conditions.

For some types of ichthyosis, the abnormal gene has been identified and prenatal testing is available. Several autosomal recessive congenital ichthyoses may be detected by prenatal testing such as:

- Lamellar ichthyosis (LI)
- Autosomal recessive lamellar ichthyosis (ARLI)
- Congenital ichthyosiform erythroderma (CIE)
- Non-bullous congenital ichthyosiform erythroderma (NBCIE)
- Harlequin ichthyosis

Genetic testing is available for many genetic mutations that cause ichthyosis. Once a couple has had a child with ichthyosis, and they have had the genetic cause identified by DNA studies (performed from a small blood sample), prenatal testing for future pregnancies may be considered. Prenatal testing may not be possible if both mutations cannot be identified. Prenatal diagnosis is available via either chorionic villus sampling (CVS) or amniocentesis. CVS is a biopsy of the placenta performed in the first trimester of pregnancy under ultrasound guidance. Ultrasound is the use of sound waves to visualize the developing fetus. The genetic makeup of the placenta is identical to the fetus and therefore specific genes can be studied from this tissue. There is approximately a 1 in 100 risk of miscarriage with CVS. Amniocentesis is a procedure done under ultrasound guidance in which a long, thin needle is inserted through the mother’s abdomen into the uterus, to withdraw a couple of tablespoons of amniotic fluid (fluid surrounding the developing baby) to study. Genetic material can be studied using cells from the amniotic fluid. Other genetic tests, such as a chromosome analysis, may also be performed through either CVS or amniocentesis.

Some congenital ichthyosis syndromes may also be detected by prenatal ultrasound. Specific fetal measurements and features such as foot length, persistently open mouth, dense amniotic fluid, and fixed flexion of the extremities may be early symptoms of ichthyosis like harlequin ichthyosis.

Treatment and management

Most treatments for ichthyosis are topical, which means they are applied directly to the skin, not taken internally. Some forms of ichthyosis require two forms of treatment—a reduction in the amount of scale buildup and moisturizing of the underlying skin. Several agents are available for each purpose. Reduction in the amount

of scales is achieved by keratolytics. Among this class of drugs are urea, lactic acid, and salicylic acid. Petrolatum, 60% propylene glycol, and glycerin are successful moisturizing agents, as are many commercially available products. Increased humidity of the ambient air is also helpful in preventing skin dryness.

Because the skin acts as a barrier to the outside environment, medicines have a hard time penetrating, especially through the thick skin of the palms of the hands and the soles of the feet. This resistance is diminished greatly by maceration (softening the skin). Soaking hands in water macerates skin so that it looks like prune skin. Occlusion (covering) with rubber gloves or plastic wrap will also macerate skin. Applying medicines and then covering the skin with an occlusive dressing will facilitate entrance of the medicine and greatly magnify its effect.

Secondary treatments are necessary to control pruritus (itching) and infection. Commercial products containing camphor, menthol, eucalyptus oil, aloe, and similar substances are very effective as antipruritics. If the skin cracks deeply enough, a pathway for infection is created. Topical antibiotics like bacitracin are effective in prevention and in the early stages of these skin infections. Cleansing with hydrogen peroxide inhibits infection as well.

Finally, there are topical and internal derivatives of vitamin A called retinoids that improve skin growth and are used for severe cases of acne, ichthyosis, and other skin conditions.

This condition requires continuous care throughout a lifetime. Properly treated, in most cases it is a cosmetic problem. There are a small number of lethal forms, such as harlequin fetus.

Imprinting

Definition

Genetic imprinting is the differential expression of a gene depending on whether it was maternally or paternally inherited. It is a method for silencing gene expression, making the gene nonfunctional. Imprinting is believed to play a critical role in fetal growth and development, but its exact role is unclear. Imprinting can sometimes lead to genetic disorders.

Description

Normal genetic imprinting process

A gene is made up of long sequences of DNA. The DNA is transcribed into messenger RNA (mRNA), and the mRNA is translated into protein. Some genes are constitutively (continually) transcribed. Others are transcribed only when their protein products are required.

Genetic imprinting is a natural phenomenon that does not follow the pattern of traditional Mendelian genetics. According to Mendelian genetics, an individual inherits two functional copies (alleles) of every non-sex-linked gene. One copy is paternally inherited, and the other is maternally inherited. When genes follow the Mendelian inheritance pattern, both the paternal and maternal copies are functionally expressed, regardless of which parent the copy came from. Imprinting, however, results in the preferential expression of some alleles

depending on their parental origin. For this reason, genetic imprinting is sometimes called the parent-of-origin effect. A gene is imprinted when its expression depends on the sex of the parent that transmitted the copy of the gene. Usually, one allele is partially or completely silenced, either temporarily or permanently, so that only one parental copy is active. Genes that are silenced are not transcribed and translated and so exert no effect on the biological system. Genes may be imprinted in some cells and tissues and not in others, because imprinting can change when cells differentiate and become specialized. For example, some genes are imprinted or silenced only in certain regions of the brain.

Imprinting of genes occurs during the formation of the parental egg or sperm. Imprinting occurs in each generation when new egg and sperm cells are produced. A female that inherits a paternally imprinted gene will maintain the paternal imprint. However, when she eventually forms her own new egg cells (gametes), the original paternal imprint may be erased and replaced with her own imprinted patterns. The same is true for males who inherit maternally imprinted genes. Thus, imprinting is not permanent, since it may be erased when gametes (eggs or sperm) are formed. This germline conversion process is regulated by the imprinting center, a piece of DNA located within the imprinted chromosome. Relatively few human genes are imprinted, and they tend to cluster together in the same genomic regions. Imprinted genes have signals that are recognized by the cellular machinery as “active” or “silenced.” The signal is often a methyl group (CH_3) that is added to a base of DNA in a process called methylation, which causes it to be silenced. These signals are referred to as “epigenetic,” because the alterations do not involve changes in the DNA sequence.

Genetic imprinting is thought to play a role in the transmission of nutrients from the mother to the fetus and to the newborn. Imprinted genes also impact fetal growth and the behavior of the newborn infant. It has been suggested that imprinting ensures that one allele of a gene is preferentially active at a given stage of development, so that the other allele is preserved for epigenetically distinct regulation at a later stage in development.

Imprinting also plays an important part in the development of many diseases. However, current knowledge of the genes that carry out the imprinting, their chromosomal locations, and their interactions with other genes is limited.

Complications in the genetic imprinting process

Multiple complications can arise involving imprinted genes. Typically, if a mutation in one allele of a gene

KEY TERMS

Allele—Any of the alternative versions of a gene that are present in the population.

Angelman syndrome (AS)—A disorder caused by the deletion or absence of active imprinted genes.

Embryogenesis—The formation and growth of the embryo.

Epigenetic—A modification to DNA, such as the addition of a methyl group, that does not change the DNA sequence.

Gamete—A reproductive cell; an ovum or sperm.

Germline—The cell line from which gametes arise.

Mendelian genetics—A set of parameters describing the traditional method of the transmission of genes from one generation to the next.

Methyl group (CH_3)—A molecule of one carbon and three hydrogen atoms that can be attached to DNA bases as a signal for regulating gene expression.

Prader-Willi syndrome (PWS)—A disorder caused by the deletion or absence of active imprinted genes.

Spasticity—Increased muscular tone or contractions that cause stiff or awkward movements.

Uniparental disomy—The inheritance of both copies of a chromosome from one parent.

eliminates its function, the other allele can continue to function and produce the gene product. However, with an imprinted gene, if the functional allele is deleted or mutated, there is no functional backup allele; thus, mutation of the active copy of an imprinted gene may result in disease. Another complication occurs if, as a result of an error, cells receive all or part of a pair of chromosomes from a single parent. This is known as uniparental disomy. If uniparental disomy occurs with imprinted genes, the cell receives either two silenced copies or two active copies. If both copies are silenced, there is no functional copy of that gene.

Loss of gene activity and gain of inappropriate activity can both be harmful. A mutation in a silenced gene may activate that gene, resulting in two active copies when one copy should be silenced. This can result in overexpression of the gene product, which is involved in some diseases. For example, some types of cancer are associated with a failure to imprint or silence genes that encode for growth factors. Overexpression of these growth factors contributes to uncontrolled cell growth

QUESTIONS TO ASK YOUR DOCTOR

- Can you explain what is meant by imprinting?
- Could my child's disorder be caused by an imprinting error?
- What are the chances that we could have another child with an imprinting disorder?
- Can imprinting disorders be detected by genetic testing?

and the development of cancer. Environmental factors, such as exposure to toxins, can sometimes cause changes in DNA that alter imprinted gene expression, resulting in diseases such as cancer or behavioral disorders.

Two of the best-studied diseases caused by genomic imprinting are Prader-Willi syndrome (PWS) and Angelman syndrome (AS). Both syndromes are caused by alterations in chromosome 15, which contains a number of imprinted genes. PWS is a neurobehavioral disorder characterized by excessive eating, obesity, short stature, intellectual disability, and small hands and feet. Approximately 70% of PWS cases are caused by a deletion in a specific region of the paternally active chromosome 15. Since the corresponding genes on the maternal chromosome 15 are inactive, they cannot compensate for the gene deletion. These deleted genes are associated with feelings of hunger and fullness. Approximately 29% of PWS cases are caused by inheriting two maternal copies of chromosome 15, in which the genes are imprinted as inactive. About 1% of PWS cases involve a mutation in the imprinting center itself. AS is characterized by hyperactivity, an unusual facial appearance, short stature, intellectual disability, spasticity, inappropriate laughter, and seizures. Approximately 70% of AS cases are caused by a deletion of the maternal *UBE3A* gene on chromosome 15. Both copies of this gene are active in many tissues; however, in the brain only the maternal copy is active, and its deletion leads to the symptoms of AS. Other cases of AS are caused by inheriting two copies of the paternal chromosome 15 with *UBE3A* genes that have been imprinted as inactive. Beckwith Wiedemann syndrome (BWS) is a disorder associated with overgrowth and malformations due to an imprinting defect in a specific region of chromosome 11.

Imprinting and epigenetics are very active areas of research. Epigenomic maps are being developed for various cell types, tissues, and organs. Researchers hope this will lead to better prevention, diagnosis, and treatment

of disease. Researchers are also studying whether assisted reproduction techniques such as in vitro fertilization (IVF) may interfere with the imprinting process during early embryogenesis.

Incontinentia pigmenti

Definition

Incontinentia pigmenti (IP) is an X-linked dominant disorder affecting primarily the skin, hair, teeth, and nails (all components of the epidermis). This disease may have been initially described by Garrod in 1906. It was completely characterized by Bloch and Sulzberger in 1928. For this reason, incontinentia pigmenti has also been referred to as Bloch-Sulzberger syndrome.

Description

Incontinentia pigmenti has been traditionally classified into two types: type I and type II. Much debate has occurred over whether or not type I, or sporadic, incontinentia pigmenti is actually the same disease as type II, or familial, male-lethal type incontinentia pigmenti. The growing consensus is that sporadic (type I) incontinentia

Incontinentia pigmenti: pedigree analysis chart (Gale)

pigmenti is not, in fact, the same disease as familial, male-lethal (type II) incontinentia pigmenti. Type II (familial, male-lethal) incontinentia pigmenti is considered to be the “classic” case of incontinentia pigmenti that matches the disease characterized by Bloch and Sulzberger in 1928.

Genetic profile

The locus of the gene mutation responsible for incontinentia pigmenti type II has been mapped to the long end of the X chromosome at gene location Xq28. The affected gene is known as the *NEMO* gene.

A chromosome is a long chain of deoxyribonucleic acid (DNA), a double-stranded molecule composed of individual units called nucleotides. The two strands that make up a single DNA molecule are held together by a matching (base pairing) of the nucleotides on one strand with the nucleotides on the other strand. Each set of a nucleotide on one strand paired with its nucleotide on the other strand is called a base pair.

A gene is a particular segment of a particular chromosome. Within the segment containing a particular gene there are two types of areas: introns and exons. Introns are sections of the particular chromosomal segment that do not actively participate in the functioning of the gene. Exons are those sections that do actively participate in gene function. A typical gene consists of several areas of exons divided by several areas of introns.

The *NEMO* gene was completely sequenced by the International Incontinentia Pigmenti Consortium in 2000. The *NEMO* gene consists of approximately 23,000 base pairs that compose ten exons. The first exon of this gene, which is the exon that tells this gene to “turn

on,” has been found to have three variants; these are designated: 1a, 1b, and 1c.

The *NEMO* gene is known to partially overlap with the gene responsible for the production of glucose-6-phosphate dehydrogenase (*G6PD*). Mutations in the *G6PD* gene cause an underproduction of red blood cells (anemia) that results in an insufficient amount of oxygen being delivered to the tissues and organs. Anemia resulting from mutations in the *G6PD* gene is observed with higher frequencies in Africans, Mediterraneans, and Asians.

The locus of the gene mutation responsible for type I incontinentia pigmenti has been mapped to band Xp11, on the short arm of the X chromosome. Individuals affected with this disorder show many of the signs of incontinentia pigmenti type II, but it is not an inherited condition. Type I incontinentia pigmenti is only exhibited as a sporadic and *de novo* trait. This means that when an affected individual has the symptoms of type I IP, that individual did not inherit this condition from his or her parents; rather, the condition was caused by a mutation that occurred after conception.

Demographics

Incontinentia pigmenti is observed with higher frequencies in Africans, Mediterraneans, and Asians than in other portions of the population. This was originally thought to be due to the greater ability to observe the skin-related symptoms in these individuals. But, with the additional evidence that the *NEMO* gene and the *G6PD* gene overlap and that anemia resulting from mutations in the *G6PD* gene also disproportionately affects these populations, this anecdotal explanation has to be discarded.

KEY TERMS

Chromosome—A microscopic thread-like structure found within each cell of the body and consists of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

De novo mutation—Genetic mutations that are seen for the first time in the affected person, not inherited from the parents.

Exon—The expressed portion of a gene. The exons of genes are those portions that actually chemically code for the protein or polypeptide that the gene is responsible for producing.

Hyperpigmentation—An abnormal condition characterized by an excess of melanin in localized areas of the skin, which produces areas that are much darker than the surrounding unaffected skin.

Intron—A portion of the DNA sequence of a gene that is not directly involved in the formation of the chemical that the gene codes for.

Pustule—A pus-filled lesion of the skin that resembles the “pimples” of adolescent acne.

Type I incontinentia pigmenti—Sporadic IP. This disorder is caused by mutations in the gene at Xp11. These mutations are not inherited from the parents, they are *de novo* mutations. This type of IP probably represents a different disease than type II IP.

Type II incontinentia pigmenti—Familial, male-lethal type IP. This type of IP is the “classic” case of IP. It is caused by mutations in the *NEMO* gene located at Xq28. Inheritance is sex-linked recessive.

More than 95% of all patients diagnosed with IP are female. The occurrence in males is probably due to a spontaneous (*de novo*) mutation in the *NEMO* gene that is not as severe as the typical mutation leading to IP or the misdiagnosis of type I IP. Approximately 70% of all IP affected individuals have been found to have the same mutation in the *NEMO* gene. In these families, 100% lethality prior to birth is observed in males.

Signs and symptoms

Familial, male-lethal (type II) IP is characterized by progressive rashes of the skin. These have been classified into four stages: the red (erythematic) and blister-like (vesicular) stage; the wart-like (verrucous) stage; the

darkened skin (hyperpigmented) stage; and the scarred (atrophic) stage.

The first, or erythematic vesicular, stage consists of patches of red skin containing blisters and/or boils. This condition usually appears in affected individuals at or near birth and is generally localized to the scalp, the arms, and the legs. This stage generally lasts from a few weeks to a few months and may recur within the first few months of life. It rarely recurs after the age of six months. This condition is often misdiagnosed as chicken pox, herpes, impetigo, or scabies. Each of these alternative diseases is potentially life-threatening in an infant, so most IP-affected infants are treated for one of these diseases before the appropriate diagnosis of incontinentia pigmenti can be made.

The second, or verrucous, stage of IP is characterized by skin lesions that look like adolescent acne (pustules). Upon healing, these pustules generally leave darkened skin. This stage almost exclusively affects the arms and legs, but it may be observed elsewhere. The verrucous stage may occur at birth, which may indicate that the erythematic vesicular stage occurred prior to birth. But, more generally, the second stage of IP skin disorder is observed after the first stage has completed. The verrucous stage tends to persist for months. Rarely, it may last for an entire year.

The third, or hyperpigmented, stage is characterized by “marbled skin,” in which darkened areas of skin seem to make swirling patterns across the normal and less pigmented skin. This third stage generally occurs between 6 and 12 months of life. In 5%–10% of affected individuals, this third stage is present at birth. These areas of hyperpigmentation tend to fade with age such that they are barely visible in adults affected with type II IP.

Areas of scarred skin caused by the first two stages characterize the fourth, or atrophic, stage. These scars are often noticeable before the third stage has begun to fade. Adolescents and adults affected with type II IP will generally have pale, hairless patches or streaks, most visibly on the scalp or calves, that are associated with this fourth stage. In many adults affected with IP, the skin abnormalities may have faded to such a significant degree that they are no longer noticeable to the casual observer. Many type II IP affected individuals have a loss or lack of hair on the crown of the head (alopecia). This is suspected to be caused by the underlying skin atrophies of IP.

More than 80% of individuals affected with type II IP have abnormalities of the teeth including missing teeth, late eruption of both the baby teeth and the adult teeth, unusually pegged or cone-shaped teeth, and deficiencies in the enamel. A smaller percentage

(approximately 40%) of affected individuals have irregular formations of the finger and toe nails including missing nails, thickened nails, and ridged or pitted nails. In a small number of cases, the skin lesions associated with the first two stages of skin abnormalities may be present underneath a nail. In these cases, it is possible for this lesion to develop into a benign tumor that may cause abnormal bone development in the affected finger or toe.

Approximately 30% of all individuals affected with IP experience visual problems. Less than 10% of type II IP-affected individuals have vision problems related to an abnormal growth of blood vessels in the retina, which may, if untreated, lead to a detachment of the retina, possibly resulting in blindness. These symptoms generally are seen before the affected individual reaches the age of five. Other vision problems that have been observed in type II IP-affected individuals include crossed eyes or “wall eyes” resulting from an improper alignment of the eyes (strabismus); partial or complete opaqueness in one or both lens (cataract); and, occasionally abnormally small eyes (microphthalmia). Because of these vision problems, some individuals affected with IP are blind at birth or will go blind if corrective treatment is not sought.

The incidence of breast development anomalies in type II-IP affected girls is quite common. It is estimated to be more than ten times that of the general population. These anomalies range from the presence of an extra nipple to the complete absence of breasts.

Approximately 25% of all IP-affected individuals have disorders of the central nervous system. These include mental retardation, slow motor development, epilepsy, an abnormally small brain (microcephaly), and increased muscle tone in both legs (spastic diplegia) or in all four limbs (spastic tetraplegia) similar to that seen in the classic case of cerebral palsy.

Diagnosis

The genetic mutation responsible for type I incontinentia pigmenti has been fully mapped and sequenced; therefore, it is possible to perform a genetic test for the existence of this disease. However, most cases are still diagnosed on a clinical basis.

Clinical diagnosis of type I IP is based primarily on the skin abnormalities seen at birth. These skin problems may still be misdiagnosed as chicken pox or herpes. This misdiagnosis is easily corrected when the affected individual begins to develop the later stages of the skin anomalies. All suspected male infants should have a chromosome test performed to confirm diagnosis.

In older patients with scarred skin, a skin biopsy that shows “loose” melanin (the pigment that produces color in the skin) confirms a diagnosis of IP.

When the skin appears normal, a diagnosis of IP is indicated when an individual shows one or more of the physical symptoms characteristic of IP: teeth abnormalities, missing patches of hair (alopecia), and/or overgrowth and scarring of the retinal blood vessels; and, that individual is female, has two or more IP-affected daughters, is the daughter or sister of an affected woman, or has experienced the miscarriage of two or more male fetuses.

The presence of seizures within the first weeks of life indicate central nervous system involvement in the IP-affected individual and indicate an extremely high likelihood of subsequent developmental delay.

Treatment and management

Usually no treatment for the skin conditions associated with IP is necessary other than the control of secondary infection that may occur.

In a female newborn where IP is suspected, an eye exam to look for retinal abnormalities, or any of the other possible eye disorders associated with IP, should be conducted within the first few days after birth. Older affected individuals should have regular eye exams to ensure that retinal abnormalities do not develop. Laser treatments and freezing treatments (cryopexie) are often required to prevent retinal detachment.

Dental treatment is often necessary to repair damaged enamel or for cosmetic reasons in the cases of missing teeth or abnormally shaped teeth.

In cases where there is involvement of the central nervous system, the necessary treatments are on a symptomatic basis. These may include early and continuing intervention programs for developmental delays, anticonvulsants to control seizures, muscle relaxants to control spasticity, and/or surgery to release the permanent muscle, tendon, and ligament tightening (contracture) at the joints that is characteristic of longer term spasticity.

Prognosis

Incontinentia pigmenti is generally fatal in males prior to birth. Females, and the few surviving males, who are affected with IP can expect a normal lifespan if treatment is undertaken to repair or manage any of the associated symptoms.

Infertility

Definitions

Infertility is defined as the failure of a couple to conceive (or become pregnant), regardless of cause, after of year of unprotected intercourse. Some physicians consider infertility to be likely if the female partner is over 35 and has failed to conceive after six months of unprotected intercourse. Recurrent pregnancy loss (miscarriages or stillbirths) is included in the definition of infertility in the United States.

Primary infertility is defined as inability to become pregnant at all, while secondary infertility is defined as inability to become pregnant after a previously successful pregnancy.

Sterility is defined as complete inability in either a man or a woman to produce offspring. It may result from disease, physical injury, a genetic disorder, a surgical procedure to prevent conception (vasectomy in men, tubal ligation or hysterectomy in women), or exposure to radiation.

Demographics

Infertility is fairly common worldwide. In the United States, infertility affects between 10% and 15% of couples of reproductive age. Worldwide estimates range between 12% and 28% of couples, with the World Health Organization (WHO) stating that about 48 million

couples and 186 million individuals around the world are infertile.

Infertility of the male partner is responsible for 20% to 30% of infertility cases, while 20% to 35% are due to infertility in the female; and 25% to 40% of cases are due either to medical issues in both partners or to unknown causes.

General causes of infertility

In men

Causes of infertility in men may include:

- Antisperm antibodies (ASAs). These are proteins produced by the immune system, in either men or women, that mistake sperm for foreign invaders and inactivate or kill sperm. ASAs can be detected in male ejaculate or female vaginal fluids.
- Aging. Although aging plays a more important role in female infertility than in male infertility, men over age 40 are more likely to have difficulty fathering a child. It is thought that the lowered quality of sperm in older men is due to DNA damage.
- Physical trauma to the testicles.
- Structural abnormalities of the male genitalia. These may include blockages of the vasa deferentia, the ducts that carry sperm toward the ejaculatory ducts in preparation for ejaculation; obstruction of the

Color-enhanced micrograph of a karyotype of an infertile male. There are 22 pairs of chromosomes and also the gender determining pair (lower right corner). In men, this comprises one X and one Y chromosome. In women, it is made up of two X chromosomes. The Y chromosome carries genetic information responsible for the development of male characteristics. Karyotypes are an arrangement of chromosomes based on their appearance under a light microscope. (Leonard Lessin/Science Source)

ejaculatory ducts; missing or absent testis (monorchism); varicocele, an abnormal enlargement of the veins in the scrotum; hypospadias, a birth defect in which the opening of the urethra is located on the lower surface of the penis; and chordee, an abnormal downward curve to the erect penis.

- Medical conditions. These include celiac disease (CD), diabetes, cystic fibrosis, some autoimmune disorders, inflammation of the prostate gland, and infectious diseases like mumps, malaria, hepatitis B, and sexually transmitted infections (STIs) like chlamydia and gonorrhea. STIs not only can affect the quality of sperm but can also cause inflammation of the epididymis, the tube behind the testes that stores and transports sperm.
- Disorders of the hypothalamus, pituitary, and adrenal glands, including tumors of the pituitary gland, whether benign or cancerous; Cushing's syndrome, which results from heavy use of corticosteroid drugs or a tumor of the adrenal glands causing excessive cortisol production; and congenital adrenal hyperplasia (CAH), a group of disorders that affects the adrenal glands' ability to make certain specific hormones, resulting in abnormal external genitalia and early, delayed, or absent puberty.
- Medications. Drugs that are known to affect sperm production include flutamide, cyproterone, and bicalutamide (drugs used to treat prostate cancer); spironolactone (used to treat fluid retention); ketoconazole (an antifungal drug); and cimetidine (a drug given to reduce stomach acid production).
- Testicular cancer.
- Radiation or chemotherapy used to treat any form of cancer.
- Occupational exposure to radiation, pesticides, lead, cadmium, or mercury.

Lifestyle factors that can lower sperm production include obesity; heavy use of alcohol and drugs of abuse, particularly marijuana; abuse of testosterone or anabolic steroids to build muscle; smoking; strenuous bicycle or horseback riding; and frequent use of saunas and hot tubs.

In women

Causes of infertility in women may include:

- Presence of antisperm antibodies (ASAs) in vaginal fluid.
- Aging. Women's fertility peaks in the mid-20s, after which it starts to decline.
- Structural abnormalities of the female reproductive tract. These may include endometriosis, a condition in which the tissue that normally lines the uterus is found elsewhere outside the uterus, often covering the ovaries and fallopian tubes; blocked fallopian tubes (a common

result of pelvic inflammatory disease); an abnormally shaped or half-formed uterus; the presence of fibroids or polyps in the uterus; scar tissue in the uterus resulting from infections or surgery; history of ruptured appendicitis; ambiguous external genitalia as a result of CAH; lack of connection between the uterus and the cervix; vagina missing or partially blocked between the hymen and the cervix; presence of an extra ovary or tissue attached to the ovaries. Many of these abnormalities in women and girls are caused by disturbances in the development of structures called the Müllerian ducts in female embryos.

- Sexually transmitted infections (STIs). Infections like gonorrhea and chlamydia are a common cause of infertility in women in that they can lead to blockage of the fallopian tubes. Syphilis increases a woman's risk of stillbirth. Human papillomavirus (HPV) infections can affect a woman's fertility in that the removal of abnormal cells from the woman's cervix to treat HPV can affect the production of cervical mucus.
- Hormonal disorders. Polycystic ovary syndrome (PCOS) is a hormonal disorder characterized by underproduction of follicle-stimulating hormones and overproduction of androgens. Overproduction of the hormone prolactin by the pituitary gland may lead to failure to ovulate. Tumors of the pituitary, thyroid, and adrenal glands can also lead to a failure to ovulate.
- Autoimmune disorders. Such disorders as lupus, Hashimoto's thyroiditis, and rheumatoid arthritis can reduce a woman's fertility.
- Anovulation. Failure to ovulate (produce an egg during a normal menstrual cycle) can result from any of a number of factors; hormonal disorders have already been mentioned. Many teenagers do not ovulate for a year or even longer after their first menstrual period (menarche). Emotional stress can lead to a condition called functional hypothalamic amenorrhea or FHA. Inadequate nutrition, including eating disorders, is another common cause of anovulation. Premature ovarian insufficiency (POI) is a term used to describe the failure of a woman's ovaries before 40 years of age. Last, women cease to ovulate when they reach menopause, which occurs around age 50 in most women.
- Scar tissue inside the abdomen, resulting from surgery to repair traumatic injuries or remove diseased tissue.
- Radiation or chemotherapy used to treat any form of cancer.

Lifestyle factors that affect fertility in women include obesity, eating disorders, being underweight, under- or over-exercising, smoking, heavy drinking, using drugs of abuse, and high levels of emotional stress.

KEY TERMS

Amenorrhea—Absence of menstruation, usually defined as missing one or more menstrual periods.

Androgen insensitivity syndrome—An intersex condition found in people who are chromosomally male (karyotype XY) but have a mutation in the *AR* gene that makes them unable to respond to male sex hormones. As a result, they may have some or all of the physical traits of a female.

Aneuploidy—An abnormal number of chromosomes in a cell, whether extra or missing chromosomes.

Assisted reproductive technologies (ART)—A collective term for a group of procedures done to address problems with fertility. ART includes such techniques as in vitro fertilization, cryopreservation of donated gametes or embryos, and preimplantation genetic diagnosis.

Autosome—Any chromosome that is not a sex chromosome. The human genome has 22 pairs of autosomes.

Azoospermia—The absence of live sperm in male semen.

Fragile X syndrome—A genetic condition caused by a mutation in the *FMR1* gene on the X chromosome and characterized by intellectual disability.

Galactosemia—A rare genetic disorder in which the person cannot metabolize galactose, a simple sugar found in dairy products.

In vitro fertilization (IVF)—A form of assisted reproduction technology in which a human ovum (egg) is combined with sperm outside the body in a laboratory container (“in vitro” means “in a glass”).

Informed consent—The process of obtaining permission from a person before conducting a health care procedure on a person, enrolling a person in a clinical trial, or disclosing that person’s private information.

Karyotype—The complete set of chromosomes in a species or individual organism. The term can also refer to the laboratory technique used to produce an image of an individual’s chromosomes.

Klinefelter syndrome—A genetic disorder characterized by one or more extra X chromosomes in a male, with a 47,XXY, 48,XXX, or 49,XXXXY karyotype. Most men with this syndrome are infertile or have reduced fertility. The syndrome is named for Harry Klinefelter (1912–1990), an American endocrinologist who first described it in 1942.

Leiomyomas—Benign tumors in the smooth muscle tissue of the uterus. They are also known as fibroids.

Menarche—The medical term for the first menstrual period in girls, usually around age 12.

Microdeletion—A chromosome deletion that is too small to be detected by standard karyotyping methods. Microdeletions are typically one to three mega bases in

Genetic causes of infertility

Genetic disorders can cause infertility in both men and women.

In men

Genetic disorders causing infertility in men fall into several different categories:

- Defects in the number of chromosomes (aneuploidy). Infertile men may have extra sex chromosomes, as in Klinefelter syndrome (karyotype 47,XXY), which is found in up to 14% of men with azoospermia (total absence of sperm in semen); and 47,XYY syndrome, which is often characterized by oligospermia (abnormally small number of sperm).
- Abnormalities in chromosome structure. These include microdeletions on the Y chromosome, which affect sperm production; Robertsonian translocations (in which the long arms of two acrocentric chromosomes fuse), which increase the risk of trisomy 21 (Down

syndrome) in the next generation; and XX male syndrome, which is also known as de la Chapelle syndrome and 46,XX testicular difference of sex development (46,XX DSD). This syndrome is very rare; it develops when the *SRY* gene on the Y chromosome, which is essential to normal male reproductive development, crosses over to the father’s X chromosome during germ cell development. When the X with an *SRY* gene combines with a normal X chromosome from the mother, an XX male will result. Men with a 46,XX karyotype typically have abnormally small testicles and do not produce sperm.

- Single-gene disorders. These include congenital bilateral aplasia of the vas deferens (CBAVD), a condition in which the tubes that convey sperm from the testicles to the penis are missing from birth. CBAVD is associated with mutations in the *CFTR* gene. Other single-gene mutations associated with androgen insensitivity syndrome, the production of abnormally shaped sperm, or absence of sperm production have been identified in

length (one to three million base pairs), whereas standard deletions are five mega bases or longer.

Müllerian ducts—Structures found in the human embryo that develop into the fallopian tubes, the uterus, the cervix, and part of the vagina in females. They are named for Johannes Müller, a nineteenth-century German physician and anatomist.

Multifactorial disorders—A general term for polygenic disorders complicated by the effects of environmental factors. Multifactorial disorders do not have clear patterns of inheritance. They are sometimes called complex diseases or disorders. PCOS in women is a multifactorial disorder.

Oligospermia—A low concentration of sperm in a semen sample, usually defined as fewer than 15 million sperm per milliliter.

Polycystic ovary syndrome (PCOS)—A multifactorial disorder in women characterized by absent or infrequent ovulation, hirsutism (excessive body hair), infertility, acne, and increased susceptibility to obesity and type 2 diabetes.

Reproductive endocrinologist—A doctor (usually a gynecologist) with subspecialty training in hormonal functioning as it pertains to infertility.

Robertsonian translocation—A chromosomal abnormality in which the long (q) arms of two acrocentric chromosomes (chromosomes in which

the p arm is much shorter than the q arm; in humans, these are chromosomes 13, 14, 15, 21, and 22, and the Y chromosome) fuse together. The anomaly is named for William R.B. Robertson (1881–1941), who first identified it in grasshoppers in 1916.

Sterility—The inability of either a male or a female to produce offspring. Sterility may result from physical injury, disease, genetic disorders, or exposure to radiation.

Trisomy—A type of aneuploidy in which there are three copies of a specific chromosome in cells instead of the normal two. Some trisomies result in infertility.

Turner syndrome—A chromosomal disorder with a 45,X or 45,X0 karyotype that affects only females, in which one of the X chromosomes is either partially or completely missing. Most women with Turner syndrome are infertile because of a lack of ovarian function.

Varicocele—Enlargement of the veins within the male scrotum. Sometimes described as resembling a bag of worms, varicoceles are a common cause of low sperm production and reduced sperm quality.

Y chromosome—The sex chromosome (allosome) that is found together with an X chromosome in normal human males. Microdeletions in the Y chromosome can affect a man's fertility in adult life.

connection with the *AR*, *AURKC*, *HSF2*, *KLHL10*, *NR5A1*, *PRM1*, *SLC26A8*, *SOHLH1*, *SPATA16*, and *ZBPB1* genes.

In women

As in men, genetic disorders in women fall into several different categories:

- Defects in the number of chromosomes. Turner syndrome (45,X0, also known as monosomy X) is a condition in which a woman has only one X chromosome and can have children only by assisted reproductive technology (ART). 47,XXX syndrome, also known as trisomy X, is associated with premature ovarian insufficiency (POI) or abnormalities of the kidneys and urinary tract, while some women with this karyotype have normal fertility.
- Single-gene disorders. These include fragile X syndrome, caused by a mutation in the *FMR1* gene; galactosemia, a metabolic disorder, caused by a mutation

in the *GALT* gene; POI, associated with the X-linked genes *FMR1* and *BMP15* as well as with the *AR*, *CDKN1B*, *CYP19A1*, *GDF9*, *FIGLA*, *FOXL2*, *FOXO1a*, *FOXO3a*, *INHA*, *LHX8*, *NOBOX*, *NANOS3*, *FSHR*, and *SALL4* genes on autosomal chromosomes; and leiomyomas (fibroids), associated with mutations in the *MED12* gene.

- Polygenic/multifactorial disorders. Polygenic disorders are complex genetic disorders involving more than one gene; multifactorial disorders include the effects of environmental as well as genetic factors. Disorders affecting female fertility that are thought to have complex genetic linkages include endometriosis, which is known to run in families; and PCOS, a multifactorial disorder.

Diagnosis

Couples are advised to have a diagnostic workup after a year of unprotected intercourse without signs of

pregnancy if the woman is younger than 35, and after six months if she is 35 or older.

Men

A diagnostic workup for causes of infertility in men is usually done by a urologist, a physician who specializes in disorders of the urinary tract and the male reproductive system. The workup includes the following:

- Detailed personal and medical history. The doctor will ask about the patient's sexual history, including any STIs; mumps after puberty; hernia repairs or athletic injuries to the groin; use of alcohol, marijuana, and other recreational drugs; present prescription medications; urinary tract infections; impotence or premature ejaculation; other surgeries, including appendectomy; and work environment.
- Physical examination. The doctor will examine the patient's penis, testicles, and prostate gland for any signs of enlargement, abnormal texture, abnormal shape, or the presence of a varicocele in the scrotum. The doctor will also order blood tests to measure the patient's levels of testosterone and follicle-stimulating hormone (FSH). FSH is a hormone that is essential to the production of normal sperm.
- Semen analysis. The patient will be asked to provide a semen sample, which will be examined in the laboratory for the number of sperm, their ability to move (motility), their velocity, their morphology (size and shape), and the ability of the semen to liquefy after ejaculation.
- Other types of semen and sperm tests. These may be done if needed. They measure the ability of the patient's sperm to break through the outer membrane of an egg to fertilize it and to move through cervical mucus. Semen may also be tested for the presence of antisperm antibodies.

Women

A diagnostic workup for causes of infertility in women is usually done by a gynecologist and includes the following:

- Detailed personal and medical history. The doctor will ask about the patient's sexual history, including any STIs; age at menarche (first period) and characteristic menstrual patterns; previous pregnancies, if any; use of alcohol, marijuana, and other recreational drugs; present prescription medications; urinary tract infections; other surgeries, including appendectomy; eating and exercise patterns; and work environment.
- Physical examination. The doctor will examine the thyroid gland in the throat for any abnormalities as well as measuring the patient's height, weight, and hair

distribution (for evidence of PCOS or other masculinizing disorders); examine the patient's breasts; perform a pelvic examination (to check the cervix for signs of infection or unusual growths); and perform a Pap smear (to examine the cervical mucus and rule out cervical cancer).

- Blood tests and ultrasound examination. The doctor may order blood tests to measure ovarian function. These tests measure the levels of estradiol, an estrogen; FSH; and inhibin B. The ultrasound test is given to see whether ovulation has occurred. Ultrasound can also be used to look for the presence of fibroids or ovarian cysts. In some cases, the patient may be referred to a reproductive endocrinologist for further testing.
- Invasive testing. Because the female reproductive system is contained within the abdomen, special procedures may be necessary to look for structural abnormalities in the uterus, fallopian tubes, or ovaries. These procedures include hysterosalpingography (HSG), in which a contrast dye is injected into the uterus through the vagina and cervix and tracked on x-ray; and hysteroscopy, in which an endoscope is inserted through the vagina to inspect the uterine cavity.
- Laparoscopic surgery. This type of diagnostic surgery is performed under general anesthesia before or around the time of ovulation to obtain a clear view of the exterior of the ovaries, uterus, and fallopian tubes. If endometriosis is found during this surgery, it can be treated with a laser.

If the doctor suspects a genetic disorder in the patient, he or she may recommend genetic testing to look for the presence of chromosome abnormalities or single-gene mutations. The test can be ordered by the patient's urologist or gynecologist, or by a genetic counselor; it requires the patient's informed consent. This type of testing requires only a blood draw or a buccal swab, in which a few skin cells from the lining of the cheek are collected on a small brush or cotton swab.

Treatment and management

Treatment of infertility depends on its cause(s) and whether the male, the female, or both partners are affected. In some cases, treatment is relatively simple and may involve little more than discontinuing a medication that interferes with sperm production or taking a medication (usually clomiphene citrate, letrozole, FSH, or bromocriptine) to stimulate egg production. In other cases, the doctor can inject specially prepared sperm from the male partner directly into the woman's uterus through a catheter; this is known as intrauterine insemination or IUI. On the other hand, genetic disorders involving chromosome number or structure are usually not treatable.

QUESTIONS TO ASK YOUR DOCTOR

- Have any of your parents consulted you about infertility?
- If so, what advice did you give them?
- Have you ever referred a patient to a reproductive endocrinologist?
- Have you ever recommended psychological counseling for a patient who was distressed about infertility?
- In your opinion, are men or women more likely to be disturbed by infertility?

Psychological counseling

In addition to medical testing and counseling, infertile couples often benefit from psychological counseling. Infertility is a blow to the self-image of many people, as infertile people within many cultures around the world experience stigma. In addition to individual stress, infertility may lead to conflict or the breakdown of the relationship between the partners, especially when the cause is traced to one partner rather than to both or remains unknown. The website of RESOLVE: The National Infertility Association, listed under Resources below, contains links to support groups and other useful information about managing infertility stress.

Assisted reproductive technologies (ART)

If there is no effective treatment for the cause of a couple's infertility, the doctor may recommend assisted reproductive technologies or ART. ART techniques include in vitro fertilization (IVF); intracytoplasmic sperm injection (ICSI), in which a single sperm from the male partner is injected into a mature egg from the female; or the use of donated sperm and eggs to produce viable embryos via IVF.

Inheritance

Definition

Inheritance (generally) and heredity (scientifically) both refer to the transmission of genes from parent to offspring, along with the physical, behavioral, and biochemical traits/characteristics they produce.

Description

Throughout history, people have puzzled over heredity. While it is obvious that physical traits and behavioral traits are passed from parent to offspring, both in plants and animals, the puzzling aspects of heredity are the exceptions and quirks in what should be a very basic process. For instance, apparently hereditary characteristics sometimes skip a generation or two, disappear altogether, or appear in an individual or generation for the first time, seemingly from nowhere. A further mystery, the finer points of which are still being unraveled, lay in the mechanism of exactly how traits get from parent to offspring. Even more perplexing to those in the past was the occurrence/recurrence of congenital anomalies and disorders, resulting in physical and/or behavioral disability.

An illustration depicting how DNA passes along genetic disorders based on gender. (3D4Medical/Science Source)

Answers to many of the questions about heredity were deduced in the mid-nineteenth century by a scientist, Gregor Mendel, at a monastery in what is now the Czech Republic. The deductions he made from the results of his experiments came to be known as Mendel's laws of heredity, since shortened to just Mendelian inheritance. These are the patterns of inheritance, dominant and recessive, with which most people are familiar. However, geneticists have learned in recent years that even Mendel's laws are not immutable and that other non-Mendelian types of inheritance also exist.

A common misconception is that genetic is synonymous with hereditary and that the terms can be used interchangeably. In fact, while something that is hereditary is always genetic, something that is genetic is not necessarily hereditary. For example, all cancer at the most basic level is genetic, caused by errors in the genetic control of cell division and proliferation. However, only a small proportion of individuals with cancer inherited the causative gene mutation from a parent. In most cases, an

external agent (carcinogen) induces a genetic mutation in a cell somewhere in the body (e.g., tobacco smoke in a lung cell, or ultraviolet radiation in a skin cell), an error in DNA replication results in a mutation, or both. Gene mutations that occur anywhere in the body other than sperms, eggs, or their precursor cells (germline) are called somatic mutations and are not hereditary. As noted, a small percentage of cases of any particular type of cancer (usually about 5%–10% for the most common types) exhibit a hereditary pattern. Most often, it is a predisposition to developing cancer that is inherited, placing someone at increased risk for cancer. In fact, most common diseases, such as diabetes, hypertension, heart disease, and so on, are thought to follow the same general pattern as cancer, with a small percentage of cases due to heredity, most due to environmental effects acting on normal, but susceptible, variants of genes, and the remaining proportion caused by purely environmental or purely somatic genetic events.

Classifying the different types of heredity can be done in various ways. However, most people are only familiar with traditional types of Mendelian inheritance and know little or nothing about other types of heredity. Accordingly, inheritance can be classified as either Mendelian or non-Mendelian, and then further divided and subdivided on that basis.

Mendelian inheritance

All somatic cells in humans (except mature red blood cells) normally contain 46 chromosomes, in 23 pairs. Sperms and eggs carry 23 chromosomes, one of each pair. The process of sperm development is spermatogenesis, egg development is oogenesis, and the general term for both is gametogenesis. The process that is the basis for Mendelian inheritance is meiosis, which takes place only during gametogenesis (chromosome duplication and cell division in somatic cells is mitosis). During meiosis, the 46 chromosomes in precursor cells in testes and ovaries duplicate to produce a total of 92. Two cell divisions then take place, reducing the number of chromosomes per cell to 23. During spermatogenesis, the process results in four sperm, but oogenesis produces only one egg (along with two nonfunctional polar bodies with 46 and 23 chromosomes each). All eggs normally carry a single X chromosome, whereas half of all sperm carry an X, and the other half carry a Y chromosome.

Humans have 24 different chromosomes, the first 22 numbered sequentially, with the twenty-third and twenty-fourth designated as X and Y. Chromosomes 1 through 22 are called autosomes. The X and Y are the sex chromosomes, although only the Y chromosome has any effect in determining sex (gender). Although it is commonly believed that female gender is determined by an

XX chromosome constitution, and likewise males are XY, this is misleading. Male and female genders are determined by specific genes and hormonal influences. Certain genetic conditions result in males that are 46, XX, and others in females that are 46,XY. Therefore, it is appropriate and technically more accurate to state that females and males typically or usually have 46,XX and 46,XY chromosome constitutions, respectively.

Mendelian inheritance is either autosomal or sex linked and dominant or recessive. Given the small number of genes on the Y chromosome and their relative unimportance in producing genetic disease, for all practical purposes, sex-linked inheritance is equivalent to X-linked inheritance. Sex-linked inheritance should also not be confused with sex-influenced inheritance, which involves autosomal inheritance with different phenotypic results in males and females due to hormonal differences. For the purposes of the criteria and terminology that follow, genetic disorders will be assumed, rather than normal characteristics (e.g., blue eyes, brown eyes, etc.) that might follow dominant or recessive inheritance patterns.

Genetic conditions that display Mendelian inheritance are often referred to as single-gene disorders. However, this is somewhat of a misnomer, since these conditions nearly always involve two genes, one on each chromosome of a particular pair. To clarify, the word *gene* is typically used in a broad context and includes all the variations of that gene, known as alleles. For instance, there may be a single gene for eye color, with different alleles for brown, blue, green, and so on. Some changes in genes result in alleles with no functional difference, or in neutral variations, such as the eye color example. Other genetic changes (mutations) result in alleles associated with disease. If an individual has two identical alleles of a gene, they are considered homozygous; if the alleles are different, that person is said to be heterozygous. Hemizygous refers to the presence of only one allele of a gene, instead of the expected two. Males are normally hemizygous for all the genes on the X and Y chromosomes, since they have only one copy of each. Hemizygosity for an autosomal gene may cause disease, and the symptoms may be different based on whether it is the maternal or paternal allele (gene) that is missing.

Autosomal dominant

The hallmarks of autosomal dominant inheritance include:

- A disorder that is caused by an anomaly in an autosomal gene, requiring only one disease-causing allele to produce symptoms (i.e., heterozygotes affected).

- The condition affects and can be transmitted by both sexes equally.
- A carrier of the gene, whether affected or not, has a 50% chance of transmitting it to each child.
- A later age of onset, with milder symptoms and greater variability, as compared to recessive disorders (on average).
- Sporadic (isolated) cases are not uncommon and are usually the result of new mutations (no previous family history).

Some conditions (e.g., Huntington disease) display what has been referred to as true dominance, which means that individuals with one-disease allele (heterozygotes) exhibit the same signs and symptoms as individuals with two-disease alleles (homozygotes). In other conditions, the effects of the gene are additive. For example, it is not unusual for two heterozygous individuals with achondroplasia (a common dwarfing condition) to meet and have children. With each conception, there is a 25% chance the child will receive a normal gene from each parent (homozygous unaffected), a 50% chance of receiving one normal gene and one achondroplasia gene (heterozygous, affected-like parents), and a 25% chance of receiving the achondroplasia gene from each parent, which results in severe limb shortening and other skeletal problems that result in death before or shortly after birth. It could be argued that this type of situation more closely resembles autosomal recessive inheritance, with heterozygotes simply showing more pronounced symptoms than most other recessive disorders.

Other important issues complicating autosomal dominant inheritance include reduced penetrance, variable expression, and possible gonadal mosaicism in the parent of an isolated case. If each person who carries the gene for a particular disorder exhibits symptoms, the gene is said to have 100% penetrance. Therefore, reduced penetrance means that some proportion less than 100% of heterozygotes will develop detectable signs of the condition. For some disorders that have been well studied, penetrance figures at specific ages have been calculated (e.g., a disorder is 50% penetrant at age 30, 70% penetrant at age 50, and so on). Variable expression simply means that two individuals with the same disease allele, even within the same family, may show markedly different ages of onset and/or severity of symptoms.

Autosomal recessive

The hallmarks of autosomal recessive inheritance include:

- The genetic disorder is fully expressed only in individuals homozygous for the disease-causing gene.

- The disorder is usually found only in siblings, with males and females at equal risk.
- When both parents are carriers (unaffected heterozygotes), the risk in each pregnancy of having an affected child is 25%.
- An unaffected sibling of an affected individual has a 66% (two-thirds) chance of being a carrier.
- The incidence of consanguinity in general is increased in autosomal recessive disorders, with a higher likelihood the more rare the condition. Conversely, consanguinity noted in the parents of a child with an unidentified disorder suggests autosomal recessive inheritance as a possible cause.

Many sporadic cases of recessive disorders are noted, because modern families tend to be small and geographically dispersed. Unfortunately, in some cases, the only way that autosomal recessive inheritance is proved is when a second or third affected child is born.

If an affected person has children with a carrier of the same disorder, each child has a 50% risk of being affected, and a 50% risk of being a carrier. If two individuals are affected by the same genetic disorder and have children (rare, but more likely for recessive disorders involving deafness, blindness, or other symptoms that tend to bring people together), all of their children will be affected.

X-linked recessive

The hallmarks of X-linked recessive inheritance include:

- The genetic disorder in which females are carriers, and usually only males are affected.
- There is no male-to-male transmission, since males transmit an X chromosome only to daughters.
- All sons of an affected male will be unaffected, but all daughters will be carriers.
- Typically, carrier females have a 25% chance in each pregnancy of having an affected child (50% chance of transmitting the X chromosome with the disease gene, but only half of those will be passed to boys).

Unlike carriers of autosomal recessive disorders, who, at most, usually show only clinically insignificant biochemical or physical changes, female carriers of X-linked recessive disorders often show mild to moderate effects of the disorder. In rare cases, they may even be as severely affected as their affected male relatives. While it is true that females normally have two X chromosomes and males have only one, it is also true that most of one of the X chromosomes in each cell are randomly inactivated in females shortly after conception. If, by chance, most cells in the body have an active X chromosome that

carries the disease gene, a female carrier can show marked symptoms of the disorder. If the reverse is true, she will likely appear completely unaffected.

Women are considered obligate carriers if they have more than one affected son, or an affected male relative and a proven carrier daughter, or an affected son and an affected brother or maternal uncle. Women are at risk for being carriers if they have one affected son, or one affected brother, or one affected maternal uncle, or a sister with an affected son (since any of them may have a new mutation).

An isolated case of a diagnosed X-linked disorder may be the result of a new mutation in the affected individual or in the mother, or may be the result of carrier status transmitted to the mother by her mother. Clarification of this point can make the difference between 50% (mother is a carrier) and negligible (new mutation) in the recurrence risk for the next male pregnancy and in the risk for daughters or sisters to be carriers. Unfortunately, carrier status of the mother may be very difficult to determine unless reliable carrier testing is available. Molecular genetic testing is making this possible for an increasing number of diseases (e.g., Duchenne muscular dystrophy and fragile X syndrome). An isolated case of an X-linked disorder may also be the result of germline mosaicism in the mother in which some of her eggs carry the mutation and others do not.

X-linked dominant

X-linked dominant disorders are rare. Females are usually affected more mildly than males. However, since both males and females can show symptoms, the inheritance pattern may resemble autosomal dominant inheritance, with the critical difference being no male-to-male transmission in X-linked inheritance. A few X-linked dominant disorders are lethal in males (e.g., incontinentia pigmenti).

Non-Mendelian inheritance

Chromosomal heredity

For purposes of broad classification, chromosome anomaly syndromes are considered either numerical or structural. As the term implies, numerical chromosome anomalies involve a change in the total number of chromosomes in each cell, most often presenting as a trisomy, such as the most common type of Down syndrome (trisomy 21). Numerical chromosomal syndromes are not considered to be hereditary. Structural chromosome anomalies can take various forms, but most often involve a translocation of some type, either an exchange of chromosomal material between two chromosomes (reciprocal translocation), or two chromosomes attached to each other to form a single chromosome (Robertsonian translocation). Either type of translocation

KEY TERMS

Allele—One of two or more alternative forms of a gene.

Autosomal—Relating to any chromosome besides the X and Y sex chromosomes; human cells contain 22 pairs of autosomes and one pair of sex chromosomes.

Hemizygous—Having only one copy of a gene or chromosome.

Heterozygous—Having two different versions of the same gene.

Homozygous—Having two identical copies of a gene or chromosome.

Mitochondrial inheritance—Inheritance associated with the mitochondrial genome, which is inherited almost exclusively from the mother.

Penetrance—The proportion of individuals with a dominant gene mutation, expressed as a percentage, who actually exhibit recognizable signs or symptoms of the disorder.

Phenotype—The physical expression of an individual's genes.

Sex-linked—A gene located on, and thus a trait linked to, the X or Y chromosomes.

Uniparental disomy (UPD)—An unusual genetic status in an individual in which one parent is the source of both chromosomes of a pair.

can be balanced (no extra or missing chromosomal material, just rearranged) or unbalanced (missing and/or extra chromosomal material). Individuals who carry a balanced translocation have no ill health effects from it, but when they produce sperms or eggs, the translocation can be passed on in an unbalanced form, which can produce a syndrome of some type in a child or very often results in repeated pregnancy loss. There is also an equally likely chance that a sperm or egg will receive the translocation in the balanced state as the parent carries it, or receive a normal chromosome complement. Other types of structural chromosome anomalies include ring chromosomes and different types of inversions of material within a single chromosome, each of which can be hereditary and present reproductive risks.

Mitochondrial inheritance

Mitochondria are tiny structures (organelles) in the cytoplasm of cells that are the primary site of energy production. They are also the only location outside of the

nucleus that contains DNA. The DNA exists in a ring structure, with about two to ten rings per mitochondrion. Additionally, depending on cell type, there may be anywhere from several dozen to more than a hundred mitochondria per cell. Approximately 70 mitochondrial genes have been identified, many of which are associated with specific genetic disorders.

Mitochondrial inheritance is unusual in that, with rare exceptions, a person inherits all their mitochondria through the egg from their mother. Again, with few exceptions, a typical mitochondrial inheritance pattern involves an affected female who transmits the condition to all of her children, but none of her affected sons will pass on the disorder. However, this straightforward pattern is usually complicated by the fact that each mitochondrion may be mosaic for the gene mutation (e.g., five rings with the mutation and five rings with normal DNA), any particular cell is likely to be mosaic for mitochondria that are themselves mosaic, and this complicated mosaic pattern can apply to any egg that results in conception. All of which makes it nearly impossible to predict specific recurrence risks or the degree of severity if a child is affected.

Uniparental disomy

Uniparental disomy (UPD) refers to an unusual genetic status in an individual in which one parent is the source of both chromosomes of a pair. Again, before it was possible to analyze chromosomes at the microscopic (DNA) level, the logical assumption was that one chromosome of each pair is always maternal in origin and the other one paternal in origin. Through various means, this supposed rule of heredity was found to have exceptions.

There are two possible mechanisms for the occurrence of UPD. The first involves a conception in which the embryo is trisomic for a particular chromosome, and at some early stage one of the extra chromosomes is “lost” during mitotic cell division. The result is a normal, diploid cell, and every cell produced from it from that point on will also be diploid. The remaining trisomic cell(s) may produce only a small percentage of the total cells in the body (mosaicism), or they may die off completely. In any case, if the disomic (diploid) cells contain the two chromosomes contributed by either the sperm or the egg, the result is UPD. This process is sometimes referred to as trisomy rescue. The other, less likely possibility is that one gamete at conception carries an extra chromosome (24 total, which is common), but the other gamete is coincidentally missing that same chromosome. If UPD involves two identical chromosomes (the first stage of meiosis produces two pairs of identical chromosomes at each position/number), the situation is further distinguished as uniparental isodisomy. On the

other hand, if the chromosome constitution at that position is the same as the parent’s, it is termed uniparental heterodisomy. Uniparental isodisomy presents a much greater risk of transmitting an autosomal recessive disorder than does the alternative.

Gonadal mosaicism

Just as individuals may be mosaic for chromosome anomalies, such as mosaic Down syndrome, so also can mosaicism for single-gene anomalies exist. Mosaicism can have both medical (the individual’s health) and reproductive (the individual’s children’s health) implications. Medical significance is determined by the degree of somatic mosaicism, while reproductive risks depend on the presence or absence of gonadal (germline) mosaicism. A person may have either type of mosaicism, but most cases probably involve both. While the presence of mosaicism in a particular tissue can be proved, the actual level (percentage of abnormal cells) can never be determined, since doing so would require genetic testing of every cell. Likewise, without testing every cell, the absence of mosaicism cannot be confirmed.

Epigenetic effects (imprinting)

Epigenetics is the study of heritable changes in gene expression that occur without a change in DNA sequence. Imprinting, the selective deactivation of certain genes in sperm and others in eggs, is the best-known and most dramatic epigenetic effect. There is also mounting evidence that certain maternal biochemical or physical influences on the embryo/fetus may alter the function of some genes. As a general rule, imprinting is removed and then reapplied during gametogenesis. It remains to be seen whether other types of epigenetic effects are similarly reversible. However, the discovery of new exceptions to old rules continues, with no evidence of slowing down.

Inherited arrhythmia

Definition

Inherited arrhythmia, also known as cardiac channelopathy, is an inherited disorder affecting the ion channels of the heart and leading to an irregular heartbeat. Symptoms of the disorder range from no symptoms at all to sudden cardiac death, particularly when undiagnosed and untreated. Types of inherited arrhythmias include congenital long QT syndrome (LQTS), short QT syndrome, Brugada syndrome, and catecholaminergic polymorphic ventricular tachycardia (CPVT).

Description

The cardiac cycle is a complex cycle involving many channels, valves, chambers, and neurological events with the end goal of circulating blood throughout the body for tissue oxygenation. The cardiac cycle is generated by cardiac action potentials, which are neurological events that communicate from the brain to the nerve to the desired cell in order for the cell to do its specific job. These action potentials occur in the myocytes for the ultimate goal of causing them to contract. Within myocytes, cardiac action potentials are propagated through the correct amount and flow of ions, particularly sodium, calcium, and potassium. Potassium ions leave the cell via channels, causing the cell to become more negative. This allows for sodium and calcium ions to come in through their own channels. When the correct number of ions inside and outside of the cell is reached, an action potential is propagated, and the cell contracts. This event occurs in a pattern throughout the heart for the proper function of the atria, ventricles, and valves, all of which work together to oxygenate blood and pump it to the rest

of the body. An arrhythmia is any disruption to this pumping of the blood, due to either an issue with the cardiac action potential or a step in the cardiac cycle itself.

Cardiac arrhythmia is the broad term for an alteration in the beat or rhythm of the heart. There are two main types of arrhythmias: bradycardia (slower heartbeat than normal) and tachycardia (faster heartbeat than normal), where normal heart rate is considered as 60 to 100 beats per minute. An arrhythmia may occur congenitally due to birth defects in the heart or a mutation in a gene such as *DPP6*. An arrhythmia may also develop in life insidiously, due to drugs or smoking or after a cardiac event such as a heart attack.

The most common types of inherited arrhythmias include long QT syndrome, short QT syndrome, Brugada syndrome (a ventricular arrhythmia), early repolarization syndrome, and catecholaminergic polymorphic ventricular tachycardia. All of these syndromes are related to a defect in one or more genes, causing a channelopathy.

Genetic profile

Inherited arrhythmia is an autosomal dominant hereditary disorder, though it has been seen to be inherited as an autosomal recessive or *de novo* mutation. Sequencing studies have shown a link between inherited arrhythmia and the *DPP6* gene located on the long arm of chromosome 7. The *DPP6* gene codes for dipeptidyl aminopeptidase-like protein-6, which is a protein that helps regulate potassium channels in the heart, specifically in the repolarizing event of the cardiac action potential. When this gene is not coded correctly, these channels do not allow the correct amount of potassium to leave the cell, keeping the cell less negative than it should be and leading to an action potential that is not properly propagated. Long QT syndrome, one type of inherited

How normal and irregular heartbeats appear on a heart monitor. (Shutterstock/Simple Deigns)

KEY TERMS

Arrhythmia—Abnormal heart rhythm; examples are a slow, fast, or irregular heart rate.

Bradycardia—An irregularly slow heartbeat.

Channelopathy—A disease caused by disturbed function of ion channel subunits or the proteins that regulate them.

Tachycardia—An excessively rapid heartbeat; a heart rate above 100 beats per minute.

arrhythmia, is related to 13 gene mutations, most of which encode for cardiac ion channels. Three out of these 13 genes—*LQT1*, *LQT2*, and *LQT3*—account for approximately 75% of the cases of LQTS. Brugada syndrome is associated with 12 gene alterations with 30% of the cases due to a mutation in the *SCN5A* gene, which is located on the short arm of chromosome 3 and makes sodium channels. Short QT syndrome is associated with mutations in the *KCH2*, *KCNJ2*, and *KCNQ1* genes, all of which make ion channels. Early repolarization syndrome (ERS) is associated with six different genes (most notably *KCNJ8*, which codes for inward potassium protein channels), and catecholaminergic polymorphic ventricular tachycardia (CPVT) has a 60% association with *RYR2*, which helps form calcium channels.

The potassium channel *KCNQ1* plays a critical role in the cardiac action potential. Inherited mutations resulting in loss of channel function or gain of function (GOF) cause heart rhythm abnormalities. A study that surveyed known disease-linked GOF mutations in *KCNQ1* found that seven of 15 increased the amount of *KCNQ1* that reached the cell surface, an effect called supertrafficking. A particular supertrafficking mutant channel, R231C, had plasma membrane levels five times the wild-type channel. Whole-cell electrophysiology noted that the R231C channel is incorrectly always open, but that its open-state current is only 20% that of the wild-type channel. The GOF of R231C reflects the combined effects of supertrafficking, constitutive channel activation, and reduced ion flux.

Researchers have used the zebrafish (*Danio rerio*) to identify the role of a gene involved in cardiac rhythm, which may help explain the fundamentals of what it takes to make a human heartbeat. A study from the University of Melbourne found that mutation of the gene *Tmem161b* causes potentially fatal cardiac arrhythmia. *Tmem161b* appears to play a central function and may be important in more than just controlling heart rhythm. If it is found to be significant in humans, it could also provide a new

candidate for genetic screening of patients with cardiac arrhythmias.

Demographics

The prevalence of inherited arrhythmias is relatively low, ranging from one in 500 to one in 2,500. Brugada syndrome, for example, is estimated to affect five in 10,000 people worldwide, with a high incidence in Asians. It is found far more often in men than in women, which could be indicative of hormonal involvement.

Signs and symptoms

The first signs and symptoms of an arrhythmia include palpitations, syncope (fainting, loss of consciousness) with spontaneous recovery, seizures, chest pain, and altered breathing. These may occur spontaneously or during physical triggers such as exercise or strenuous activity, fever, or emotional triggers such as stress or alarm from loud, unexpected noises. Arrhythmias may even occur during sleep.

Diagnosis

The diagnosis of inherited arrhythmia is made via diagnostic tools such as an echocardiogram (ECG), which detects any change in the rhythm of the heart, either at rest, in transition from lying to standing, or during exercise with or without an infusion of anti-arrhythmic drugs such as ajmaline.

Once a diagnosis is made via physical examination and diagnostic testing, genetic testing is done to further diagnose the patient and is considered the current gold standard for testing of inherited arrhythmia.

Treatment and management

Treatment and management of inherited arrhythmias include lifestyle modification, pharmaceuticals, devices such as an implantable cardioverter defibrillator (ICD), and, in some cases, surgical procedures. The most utilized pharmaceutical agents include beta blockers and sodium channel blockers. Beta blockers are used for decreasing blood pressure, thus decreasing the amount of stress placed on the heart. Recent studies correlating inherited arrhythmia with a disturbance to the *DPP6* gene and the potassium channels essential to the repolarizing event of the cardiac action potential have determined that drugs that directly inhibited said channels have a therapeutic effect on heart rate, increasing the heart rate and correcting the pumping of blood, thus correcting the arrhythmia. These drugs include dalfampridine and cilostazol, especially when coupled with secondary therapies such as quinidine, enoxaparin, warfarin, and potassium.

QUESTIONS TO ASK YOUR DOCTOR

- Should all of my immediate family members be screened for this disorder?
- What lifestyle modifications do I need to maintain?
- How often should I be assessed by my doctor?
- Which type of arrhythmia do I have, and what treatment options are best for me?

Depending on the high risk of the individual as seen in the signs and symptoms of the case, particularly with a high number of syncope episodes, frequent monitoring will be necessary. An implantable cardioverter defibrillator may also be utilized, which gets the heart back to the correct rhythm before a major cardiac event occurs. Monitoring is also important because arrhythmias due to physical or emotional triggers can be fatal. Triggers, even when the arrhythmia is latent, include stress, drugs, electrolyte imbalances, exercise, and fevers.

Lifestyle changes are particularly important in the management of arrhythmia. They include dietary changes to keep a normal weight, limiting intake of caffeine and alcohol, and limiting foods associated with high blood pressure, high cholesterol, and heart disease. Proper physical exercise and decreasing stress levels are also important factors and are necessary lifestyle modifications for the management of arrhythmias and the prevention of further cardiac damage.

Prognosis

The prognosis of inherited arrhythmia is good to very good when there is an early diagnosis. In some cases, inherited arrhythmia in infancy may cause death due to the lack of symptoms and/or absence of diagnosis. Recent studies have determined that the incidence of sudden cardiac death in persons under age 40 is approximately three in 100,000, many of which are due to hereditary factors. This information highlights the importance of familial genetic testing when there is known inherited arrhythmia in the immediate family.

Jackson-Weiss syndrome

Definition

Jackson-Weiss syndrome (JWS) is a hereditary disease of varying severity characterized by face and foot abnormalities and the premature fusion of skull bones (craniosynostosis). JWS is one of eight conditions of the FGFR-related craniosynostosis disorders.

Description

Jackson-Weiss syndrome is characterized by a small midface, unusual skull shape, and foot abnormalities. The feet display very wide big toes and webbing of the skin between the second and third toes. Additionally, the toes are angled inward. Bony foot defects apparent on x-ray include short, wide foot bones and fusion of some of the foot and ankle bones.

The hallmark skull differences associated with JWS are caused by the premature closure of skull sutures, or skull plates. Other features include a small jaw, flattening of the nasal bridge and the middle third of the face, and a beaked nose. The eyes may be crossed and are widely set and slanting downward with droopy eyelids. High arching of the roof of the mouth or cleft palate, an incomplete closure of the roof of the mouth, may also be present. Intellectual disability has been reported in some individuals with JWS.

Genetic profile

JWS is inherited in an autosomal dominant manner. This means that possession of only one copy of the defective gene is enough to cause disease. When a parent has JWS, each of his or her children has a 50% chance to inherit the disease-causing mutation. JWS is believed to have a high rate of penetrance. This means that almost all people who inherit the altered gene will manifest symptoms. JWS has also occurred spontaneously in

babies with no family history of it or any similar disorder. This is known as a sporadic occurrence.

JWS has been associated with mutations in the *FGFR2* (fibroblast growth factor receptor 2) gene that provides instructions for making a protein also called fibroblast growth factor receptor 2. This protein is involved in important processes such as cell division, regulation of cell growth and maturation, formation of blood vessels, wound healing, and embryonic development.

JWS is caused by one of several mutations that change single amino acids in the FGFR2 protein. Each of these mutations occurs in a region of the FGFR2 protein known as the IgIII domain, which is required for receiving signals and interacting with growth factors. It is believed that the mutations appear to overstimulate signaling by the FGFR2 protein, which promotes premature fusion of skull bones and affects the development of bones in the feet.

Demographics

JWS has been described in different races and geographic regions. The original Jackson-Weiss family was a large Amish family with at least 138 affected members. JWS affects both sexes equally. The strongest risk factor for JWS is a family history of the disorder. As of 2015, the incidence of JWS was still unknown. The overall incidence for all forms of craniosynostosis is estimated at 1 in 2,000 to 1 in 2,500 live births.

Signs and symptoms

Jackson-Weiss syndrome's hallmarks are variable skull differences, flattened midface, and wide big toes that angle inward toward each other. The hands are usually not involved. Rarely, deafness or intellectual disability can be seen in people with JWS.

Skull abnormalities vary between individuals. Abnormalities in skull shape happen when the sutures, or open seams between the bony plates that form the skull, fuse before they normally would (craniosynostosis). Growth of

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Autosomal—Relating to any chromosome besides the X and Y sex chromosomes. Human cells contain 22 pairs of autosomes and one pair of sex chromosomes.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted through the either mother's vagina or abdominal wall and a sample of cells is collected from around the fetus. These cells are then tested for chromosome abnormalities or other genetic diseases.

FGFR-related craniosynostosis—A group of eight disorders, including Pfeiffer syndrome, Apert syndrome, Crouzon syndrome, Beare-Stevenson syndrome, *FGFR2*-related isolated coronal synostosis, Jackson-Weiss syndrome, Crouzon syndrome with acanthosis nigricans (AN), and Muenke syndrome (isolated coronal synostosis), all caused by a mutation of an *FGFR* gene.

Sporadic—Isolated or appearing occasionally with no apparent pattern

the brain pushes outward on skull plates that have not yet fused. In JWS different sutures may be involved, leading to different head shapes. The face may be lopsided due to skull deformity.

Facial differences also vary between individuals with Jackson-Weiss syndrome. Some individuals have no obvious facial differences. The hallmark face of Jackson-Weiss syndrome has very prominent, bulging, down-slanting, sometimes crossed eyes that are slightly farther apart than normal with droopy eyelids. The middle third of the face is underdeveloped and somewhat flattened with a beaked nose. The forehead is rounded prominently, and the hairline may be slightly lower on the forehead than usual. The chin may be small, and the lower jaw may come forward more than normal. Some people with JWS may have a cleft palate or a steeply arched palate (roof of the mouth). These changes may

cause unusually nasal sounding speech or more serious speech difficulties.

The feet display unusually wide big toes that curve inward toward each other. The large bones of the foot may be fused or abnormally shaped. Smaller bones of the feet and toes may be abnormally shaped or absent. These bony abnormalities may be obvious only on x-ray. The fingers and toes may be abnormally short with webbing of the skin between the second and third toes. Extra toes may be present at birth.

Diagnosis

Characteristic facial features and unusual toes may be obvious to an untrained eye, but a thorough physical exam by a physician is necessary to check for less obvious differences. Bony differences may not be obvious, appearing only on x-ray. Bony differences in the feet were found consistently, even in seemingly unaffected individuals, in the original Jackson-Weiss syndrome family. X-ray is considered to be a very important element in diagnosing JWS. X-rays are also important in determining what specific type of abnormal skull plate fusion is present.

DNA testing is available for Jackson-Weiss syndrome. This testing is performed on a blood sample in children and adults to confirm a diagnosis made on physical features. Prenatal genetic testing is also available. An unborn baby can be tested for JWS with DNA extracted from cells obtained via chorionic villus sampling or amniocentesis.

Treatment and management

There is no medication or cure for Jackson-Weiss syndrome. Treatment, if necessary, depends on an individual's symptoms. Surgery is always offered to correct the most severe physical complications, like cleft palate. Foot and facial abnormalities can also be treated with surgery if they are bothersome to an affected individual. Cosmetic surgery on the face can yield excellent results. In many cases facial differences are so mild that surgical intervention is not recommended. Counseling and support groups may be helpful to patients experiencing emotional difficulty due to physical differences.

Genetic counseling is offered to persons who have this inheritable disorder. Parents with this disease have a 50% chance of passing it to each of their children. Prenatal diagnosis for JWS is available. This prenatal genetic testing cannot, however, predict the severity or scope of an individual's symptoms. In the future, parents with genetic diseases like Jackson-Weiss syndrome may be able to opt for disease diagnosis from a cell of an embryo before the embryo is introduced to the mother's womb.

QUESTIONS TO ASK YOUR DOCTOR

- Will my child be intellectually disabled?
- How much surgery will my child need?
- Will my child be able to walk normally?

This testing is called preimplantation genetic diagnosis and is already available in some centers in the United States.

Prognosis

The lifespan of individuals with JWS is normal. Intelligence is often normal, although borderline intelligence and intellectual disability have been described in some patients with JWS.

Jacobsen syndrome

Definition

Jacobsen syndrome is a rare chromosome disorder that affects multiple aspects of physical and mental development.

Description

Jacobsen syndrome is characterized by a distinctive facial appearance, some degree of mental impairment, and certain other types of birth defects, especially of the heart. Other common medical complications include failure to thrive, recurrent infections, decreased platelet counts, and slow growth. The syndrome derives its name from the Danish physician Petra Jacobsen, who first described an affected child in 1973. It is also known as 11q deletion syndrome, 11q terminal deletion disorder, or partial 11q monosomy syndrome. This is because the end of the long arm (q) of one copy of chromosome 11 is missing in the syndrome, so an affected person has only one copy of the genes in that region. It is the loss of these genes that leads to the multiple problems of Jacobsen syndrome.

Genetic profile

The loss of genetic material from a specific segment of chromosome 11q, which includes at least the critical region at band 11q24.1, leads to the manifestations of Jacobsen syndrome. There are several ways in which this portion of chromosome 11 can be deleted. In at least two-thirds of Jacobsen syndrome cases there is a partial chromosome 11q deletion (a terminal deletion) that begins at band q23 and extends through the end of the chromosome. The remainder of cases are attributed to the loss of this chromosome 11q genetic material due to a deletion within, but not including, the end of the chromosome (an interstitial deletion) or due to a chromosomal rearrangement, such as an unbalanced chromosome translocation or a ring chromosome.

Most deletions and chromosome rearrangements responsible for Jacobsen syndrome are not familial; they are the result of a new, or *de novo* genetic change that occurred in the gamete (the egg or sperm) contributed by the mother or father of the affected individual. Less often, the origin of the chromosome deletion or rearrangement is familial. In a minority of cases, a parent of an affected child has a folate-sensitive fragile site at chromosome band 11q23.3 that can cause chromosome breakage and subsequent deletion of chromosome 11q in a child. In a few cases, a child has inherited an unbalanced chromosome translocation from a parent who was a balanced translocation carrier.

KEY TERMS

Band—A specific region of a chromosome that is identified by its characteristic staining pattern and location within a chromosome, as seen in a karyotype. A band is either part of the short arm (p arm) or the long arm (q arm) of a chromosome and is further defined by a numeric location, such as chromosome band 11q24.1.

Chromosome—A microscopic thread-like structure found within each cell of the body and consisting of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Coloboma—A birth defect in which part of the eye does not form completely.

Congenital—Refers to a disorder that is present at birth.

Cranial suture—Any one of the seven fibrous joints between the bones of the skull.

Craniosynostosis—Premature, delayed, or otherwise abnormal closure of the sutures of the skull.

Deletion—The absence of genetic material that is normally found in a chromosome. Often, the genetic material is missing due to an error in replication in an egg or sperm cell.

Echocardiogram—A noninvasive technique that uses ultrasonic waves to examine the various structures and function of the heart.

Failure to thrive—Significantly reduced or delayed physical growth.

Folate-sensitive fragile site—A chromosome location that, under folate-deficient conditions, appears as a gap in a chromosome and is susceptible to breakage.

Gastroesophageal reflux—The return of the contents of the stomach back up into the esophagus.

Gene—A building block of inheritance that contains the instructions for the production of a particular protein and is made up of a molecular sequence found on a section of DNA. Each gene is found at a precise location on a chromosome.

Inguinal hernia—A condition in which part of the intestines protrudes through a tear in the muscles of the abdomen.

Karyotype—A photographic representation of the full set of chromosomes numbered and arranged in pairs.

Microarray—A supporting material (usually glass or plastic) to which DNA fragments of known sequence are attached for the identification and sequencing of DNA samples.

Monosomy—Missing an entire copy of a chromosome or a piece of one copy of a chromosome.

Otitis media—Inflammation of the middle ear, often due to fluid accumulation secondary to an infection.

Pancytopenia—An abnormal reduction in the number of erythrocytes (red blood cells), leukocytes (a type of white or colorless blood cell), and blood platelets (a type of cell that aids in blood clotting) in the blood.

Pyloric stenosis—Narrowing of the stomach due to thickening of the pyloric muscle at the end of the stomach.

Ring chromosome—An abnormal chromosome in which the terminal ends of the short (p) and long (q) arms have been lost and the remaining p and q arms subsequently join to form a ring.

Strabismus—An improper muscle balance of the ocular muscles resulting in crossed or divergent eyes.

Thrombocytopenia—A persistent decrease in the number of blood platelets; usually associated with hemorrhaging.

Translocation—The transfer of one part of a chromosome to another chromosome during cell division. A balanced translocation occurs when pieces from two different chromosomes exchange places without loss or gain of any chromosomal material. An unbalanced translocation involves the unequal loss or gain of genetic information between two chromosomes.

Trigonocephaly—An abnormal development of the skull characterized by a triangular-shaped forehead.

Demographics

Although it is not known how many people have Jacobsen syndrome, estimates are that 1 person in every 100,000 is affected by the disorder. Females with Jacobsen syndrome outnumber males by 3 to 1.

Signs and symptoms

Symptoms of Jacobsen syndrome are variable, and the prognosis for an affected child depends on the presence of life-threatening birth defects or other medical problems. Individuals with Jacobsen syndrome have a

distinctive physical appearance. The face is characterized by wide-spaced eyes (hypertelorism), droopy eyelids (ptosis), redundant skin covering the inner eye (epicanthal folds), a broad or flat nasal bridge, a short nose with upturned nostrils, a small chin (micrognathia), low-set ears, and a thin upper lip. As many as 90%–95% of affected individuals have a malformation of the skull called trigonocephaly, a defect that results from premature closure of one of the cranial sutures. More than one-third of individuals have a small head (microcephaly). Overall, individuals with Jacobsen syndrome are smaller than their peers or siblings. Prenatal growth retardation occurs in about 75% of fetuses. A newborn with Jacobsen syndrome is usually small at birth and continues to have delayed growth and short stature. Feeding problems that can result in failure to thrive are also common.

Children with Jacobsen syndrome usually have some degree of developmental delay or intellectual disability, ranging from mild to severe. Nearly all affected individuals also have decreased muscle tone (hypotonia) or increased muscle tone (hypertonia), as well as fine and gross motor delays. Occasionally, brain abnormalities are present.

Multiple types of physical abnormalities are known to occur in individuals with Jacobsen syndrome. Congenital heart disease is present in about half of affected children and, if severe, can pose a significant health problem. Other common internal abnormalities include pyloric stenosis, undescended testes, inguinal hernia, kidney defects, and urinary tract abnormalities. Craniofacial abnormalities such as strabismus, ptosis, colobomas (eye fissures), a high-arched palate, and external ear anomalies are frequent. Orthopedic problems, primarily joint contractures and abnormalities of the digits (the fingers and toes), have been described in some cases.

In addition to congenital defects, there are a variety of other health problems found in individuals with Jacobsen syndrome. Illnesses including recurrent respiratory infections, sinusitis, and otitis media (middle ear inflammation) occur more frequently in children with Jacobsen syndrome. Gastrointestinal problems such as gastroesophageal reflux and chronic constipation may occur. Blood disorders such as thrombocytopenia and pancytopenia are often seen in childhood but may improve with time.

Diagnosis

Most individuals with Jacobsen syndrome are diagnosed after birth. The diagnosis is usually made by a blood test called karyotyping that analyzes the chromosomes of an infant or child with intellectual disability and an atypical facial appearance. The karyotype will

QUESTIONS TO ASK YOUR DOCTOR

- What does the term “11q deletion syndrome” mean?
- What are the most serious health risks faced by a child with Jacobsen syndrome?
- At what point in a child’s development can Jacobsen syndrome be diagnosed, and how is that diagnosis made?
- Are treatments available for Jacobsen syndrome and if so, what are they and at what stage of a child’s life should they be implemented?
- What are the risks of having a second child with Jacobsen syndrome?

show a deletion or rearrangement of the longer segment (q arm) of one copy of chromosome 11. Jacobsen syndrome can be diagnosed before birth through amniocentesis after an ultrasound has indicated one or more fetal abnormalities. Another technique, known as FISH (fluorescent in-situ hybridization), may be used to further define the chromosome 11q deletion breakpoints. A study published in 2012 found that microarray analysis of amniotic fluid detected Jacobsen syndrome and various other disorders that were missed by standard karyotyping, which cannot detect smaller chromosome abnormalities.

Treatment and management

There is no cure for Jacobsen syndrome, nor is there a therapy that can replace the missing genes from the deleted segment of chromosome 11. In addition to routine pediatric exams, there are management strategies and treatments that aim to prevent or minimize some of the serious health consequences associated with Jacobsen syndrome.

At the time of diagnosis, a series of evaluations should be undertaken to appropriately guide medical management. Pediatric specialists in genetics, cardiology, orthopedics, ophthalmology, and neurology should be consulted, especially since some problems can be treated if caught early. In addition to karyotyping, important tests may include an echocardiogram of the heart, a renal sonogram, platelet and other blood counts, brain imaging studies, hearing and vision screenings, and dental exams.

A neurodevelopmental evaluation should be initiated in infancy or at the time of diagnosis with implementation of age-appropriate early intervention services such as

speech therapy, occupational therapy, and physical therapy. An ear, nose, and throat specialist (ENT) may be needed to treat problems such as otitis media. Craniofacial and neurosurgery consults may be indicated if trigonocephaly or other forms of craniosynostosis are present.

Some children may require a gastroenterology specialist to evaluate problems such as failure to thrive, chronic constipation, and/or severe gastroesophageal reflux, which may require surgical intervention. About half of males with Jacobsen syndrome have undescended testes that often require surgery.

Prognosis

Approximately 25% of affected children die before two years of age, mainly from cardiac defects, a tendency to bleed, or infection. Other than respiratory infections, surviving children are generally healthy. However, little is known about the life expectancy for those who live beyond age two or the course of Jacobsen syndrome in adulthood.

and Margaret Alic, PhD

Jervell and Lange-Nielsen syndrome

Definition

Jervell and Lange-Nielsen syndrome (JLNS) is a rare inherited disorder characterized by congenital deafness and cardiac arrhythmias (irregularities in the electrical activity of the heart that can lead to cardiac arrest and sudden death).

Description

JLNS results from mutations, or changes, in either one of two genes that encode proteins that combine to form potassium ion channels. One of the potassium channels is important for proper heart function. It is also critical in the functioning of the cochlea of the inner ear. People with JLNS lack this channel and, thus, are born with profound deafness in both ears, as well as with cardiac abnormalities.

JLNS was first described in 1957 by A. Jervell and F. Lange-Nielsen. It is also known by the names cardio-auditory syndrome of Jervell and Lange-Nielsen; cardo-cardiac syndrome; surdocardiac syndrome; deafness-functional heart disease; and deafness, congenital, and functional heart disease. The cardiac (heart) symptoms of JLNS are very similar to those of long-QT syndrome (LQTS), including a longer-than-normal "QT interval" on an electrocardiogram (ECG or EKG) test. Thus, JLNS is sometimes called QT prolonged with congenital deafness.

Genetic profile

JLNS is caused by mutations in either the *KVLQT1* (*KCNQ1*) gene or the *KCNE1* (*MinK* or *IsK*) gene. It is an autosomal recessive disorder, which means it occurs only in people with two copies of the mutant gene, one from each parent. The mutations in the two copies do not have to be identical. Someone who inherits one copy of the mutant gene and one copy of the normal gene has LQTS types 1 or 5.

Demographics

Although it is the third most common type of autosomal recessive hearing loss, JLNS is a very rare disorder.

KEY TERMS

Action potential—The wave-like change in the electrical properties of a cell membrane, resulting from the difference in electrical charge between the inside and outside of the membrane.

Arrhythmia—Abnormal heart rhythm; examples are a slow, fast, or irregular heart rate.

Autosomal recessive—A pattern of genetic inheritance where two abnormal genes are needed to display the trait or disease.

Beta-adrenergic blocker—A drug that works by controlling the nerve impulses along specific nerve pathways.

Cochlea—A bony structure shaped like a snail shell located in the inner ear. It is responsible for changing sound waves from the environment into electrical messages that the brain can understand, so people can hear.

Congenital—Refers to a disorder which is present at birth.

Depolarization—The dissipation of an electrical charge through a membrane.

Electrocardiogram (ECG, EKG)—A test used to measure electrical impulses coming from the heart in order to gain information about its structure or function.

Endolymph—The fluid in the inner ear.

Fibrillation—A rapid, irregular heartbeat.

Heterozygous—Having two different versions of the same gene.

Homeostasis—A state of physiological balance.

Homozygous—Having two identical copies of a gene.

Ion channel—Cell membrane proteins which control the movement of ions into and out of a cell.

QT interval—The section on an electrocardiogram between the start of the QRS complex and the end of the T wave, representing the firing or depolarization of the ventricles and the period of recovery prior to repolarization or recharging for the next contraction.

Repolarization—Period when the heart cells are at rest, preparing for the next wave of electrical current (depolarization).

Syncope—A brief loss of consciousness caused by insufficient blood flow to the brain.

Tachycardia—An excessively rapid heartbeat; a heart rate above 100 beats per minute.

Torsade de pointes—A type of tachycardia of the ventricles characteristic of Jervell and Lange-Nielsen syndrome.

Worldwide, there are an estimated 1.6 to 6 cases per one million people. Denmark, however, has a much higher incidence of JLNS, estimated at 1 in 200,000.

Because JLNS requires two copies of the abnormal gene, one from each parent, it most often is found in the offspring of related parents, such as cousins (termed a “consanguineous” marriage). Individuals who carry one copy of the abnormal gene and one normal gene copy will have LQTS, but will have normal hearing or only partial hearing loss. However, a child of two such individuals has a 25% chance of having JLNS. Thus, although JLNS occurs across racial and ethnic groups, it is more common in small isolated groups where marriage between relatives is frequent.

Signs and symptoms

The deafness associated with JLNS usually is apparent in infancy or early childhood. Although the severity of JLNS varies, children with acute JLNS are profoundly deaf in both ears.

Depending on the severity of the disorder, the cardiac symptoms of JLNS may be overlooked. Thus, people with JLNS can be at serious risk for sudden death. In addition to a prolonged QT interval on an ECG/EKG, cardiac arrhythmias, dizziness, periods of unconsciousness (syncope episodes), and seizures are common symptoms of JLNS. These symptoms most often occur upon awakening, during strenuous physical activity, or during moments of excitement or stress.

Diagnosis

Deaf children, particularly those with a family history of sudden death, syncope episodes, or LQTS, should be screened for JLNS, using an ECG to detect a prolonged QT interval. Genetic testing for JLNS is possible for high-risk individuals.

Individuals with JLNS sometimes have normal or borderline-normal QT intervals on an ECG/EKG. Additional ECGs/EKGs performed during exercise may reveal an abnormal QT interval. ECGs/EKGs of the parents may also reveal a prolonged QT interval.

QUESTIONS TO ASK YOUR DOCTOR

- Am I or my spouse in some way responsible for our son's Jervell and Lange-Nielsen syndrome?
- What is the connection between the auditory and cardiac symptoms of this disorder?
- What types of treatment for Jervell and Lange-Nielsen syndrome are recommended, and at what age should they be applied?
- Can you supply us with the name of an organization that is concerned with individuals who have Jervell and Lange-Nielsen syndrome?

Treatment and management

Since JLNS can result in sudden death, including sudden infant death syndrome (SIDS), treatment is essential. Beta blockers are the most common treatment for the ventricular arrhythmia of JLNS. Treatment with these drugs usually continues for life. Beta blockers such as propranolol are considered to be safe medications. Any side effects from propranolol are usually mild and disappear once the body has adjusted to the drug. However, beta blockers can interact dangerously with many other medications.

Surgery may reduce cardiac arrhythmias in people with JLNS. A mechanical device called a pacemaker or an automatic implanted cardioverter defibrillator (AICD) may be used to regulate the heartbeat or to detect and correct abnormal heart rhythms. Sometimes a pacemaker or AICD is used in combination with beta-blockers.

In 2000, the first cochlear implant in the inner ear of a child with JLNS was reported. The child gained limited hearing and improved speech.

Preventive measures

All individuals who have been diagnosed with JLNS must avoid reductions in blood potassium levels, such as those that occur with the use of diuretics (drugs that reduce fluids in the body). People with JLNS must also avoid a very long list of drugs and medications that can increase the QT interval or otherwise exacerbate the syndrome.

People with JLNS usually are advised to refrain from competitive sports and to practice a "buddy system" during moderate exercise. Family members are advised to learn cardiopulmonary resuscitation (CPR) in case of cardiac arrest.

Prognosis

Cochlear implants may improve the hearing of people with JLNS. The cardiac abnormalities of JLNS usually can be controlled with beta blockers. However, without treatment, there is a high incidence of sudden death due to cardiac events.

Family members of a JLNS individual should be screened with ECGs/EKGs for a prolonged QT interval, since they are at risk of having LQTS. Genetic counseling is recommended for people with JLNS, since their children will inherit a gene causing LQTS.

Margaret Alic, PhD

Joubert syndrome

Definition

Joubert syndrome is a well-documented but rare autosomal recessive disorder. It is characterized by partial

or complete absence of the cerebellar vermis (the tissue between the two cerebellar hemispheres), causing irregular breathing and severe muscle weakness. Other features of the syndrome include jerky eye movements, abnormal balance and walking, and mental handicap. There may be minor birth defects of the face, hands, and feet.

Description

Marie Joubert, whose name is given to the condition, gave a detailed description of the syndrome in 1969. She wrote about four siblings (three brothers and one sister) in one family with abnormal breathing, jerky eye movements (nystagmus), poor mental development, and ataxia (staggering gait and imbalance). X-ray examination showed that a particular section of the brain, called the cerebellar vermis, was absent or not fully formed. This specific brain defect was confirmed on autopsy in one of these individuals. The initial report also described a sporadic or spontaneous (not inherited) patient with similar findings, in addition to polydactyly. Another name for Joubert syndrome is Joubert-Bolthausen syndrome.

Genetic profile

Joubert syndrome is an autosomal recessive disorder. Autosomal means that both males and females can have the condition; the gene is not in any way linked to the sex of the child. Recessive means that both parents are carriers of a single copy of the changed (mutated) gene. Autosomal recessive disorders occur when a person inherits a mutated gene from both the mother and the father with the same defect, so that neither gene functions correctly. The chance that this will occur in children of carrier parents is 25% (one in four) for each pregnancy. There is a 50% chance with each pregnancy that the child will have one good copy of the gene and one changed or defective copy. These children will not show characteristics of the disorder, but they can pass the defective gene on to their children. There is also a 25% chance with each pregnancy that the child will have two normally functioning genes. These children will not have the disorder and will not be able to pass a defective gene on to the next generation. There have been many instances of siblings each with Joubert syndrome, although the parents appeared free of the disorder.

The cerebellum and brain stem begin to form between the sixth and twelfth week of pregnancy. The birth defects seen in Joubert syndrome appear to develop during this crucial period. The defects will affect balance and coordination later in life. Changes in at least 19 genes (and possibly as many as 30) have been implicated in the development of Joubert syndrome and several related syndromes. These genes include *TMEM67* (*MKS3*), *NPHP1*, *CEP290*

KEY TERMS

Apnea—An irregular breathing pattern characterized by abnormally long periods of the complete cessation of breathing.

Ataxia—A deficiency of muscular coordination, especially when voluntary movements are attempted, such as grasping or walking.

Cerebellum—A portion of the brain consisting of two cerebellar hemispheres connected by a narrow vermis. The cerebellum is involved in control of skeletal muscles and plays an important role in the coordination of voluntary muscle movement. It inter-relates with other areas of the brain to facilitate a variety of movements, including maintaining proper posture and balance, walking, running, and fine motor skills, such as writing, dressing, and eating.

Iris—The colored part of the eye, containing pigment and muscle cells that contract and dilate the pupil.

Nystagmus—Involuntary, rhythmic movement of the eye.

Polydactyly—The presence of extra fingers or toes.

Retina—The light-sensitive layer of tissue in the back of the eye that receives and transmits visual signals to the brain through the optic nerve.

Vermis—The central portion of the cerebellum, which divides the two hemispheres. It functions to monitor and control movement of the limbs, trunk, head, and eyes.

(*NPHP6*), *CC2D2A*, *AH11*, *RPGRIP1L*, *KIF7*, *ARL13B*, *INPP5E*, *TMEM216*, *TCTN1*, *TCTN2*, *TMEM237*, *OFD1*, *CEP41*, *C5orf42*, *TMEM138*, *TMEM231*, and *TCTN3*. A mutation in the *ANIL* gene is responsible for about 11% of cases.

The genes associated with Joubert and related syndromes produce proteins involved in the formation cilia, which are microscopic hairlike projections that develop on cells regulating chemical signaling. Presumably, malformed cilia cannot correctly sense the chemical environment surrounding the cell and direct it to send the correct chemical signals needed for proper development.

Demographics

Joubert syndrome is rare. It appears to occur in one of every 100,000 live births, although the exact incidence is difficult to determine, because the syndrome produces

QUESTIONS TO ASK YOUR DOCTOR

- What are the characteristic symptoms of Joubert syndrome?
- How is Joubert syndrome diagnosed, and at what age does this diagnosis normally take place?
- What treatments are available for Joubert syndrome?
- What is the life expectancy for a person diagnosed with Joubert syndrome, and what factors might affect that prognosis?

a wide variety of symptoms. The disorder is found worldwide, but it is slightly more common in Ashkenazi Jewish, French-Canadian, and Hutterite populations.

Signs and symptoms

The cerebellum is the second largest part of the brain. It is located just below the cerebrum and partially covered by it. The cerebellum consists of two hemispheres, separated by a central section called the vermis and is connected to the spinal cord, through the brain stem.

The cerebellum and vermis normally work to monitor and control movement of the limbs, trunk, head, and eyes. Signals are constantly received from the eyes, ears, muscle, joints, and tendons. Using these signals, the cerebellum can compare what movement is actually happening in the body, with what is intended to happen. Then, it sends an appropriate signal back. The effect is to either increase or decrease the function of different muscle groups, to make movement both accurate and smooth. At birth, infants often have low muscle tone, and as they grow, they are delayed in reaching many gross motor milestones.

In Joubert syndrome, the cerebellar vermis is either absent or incompletely formed. The brain stem is sometimes quite small. The absence or abnormal function of these brain tissues causes problems in breathing and vision as well as severe delays in development.

One characteristic feature of Joubert syndrome is the pattern of irregular breathing, which alternates between deep rapid breathing (almost like panting) and periods of severe apnea (loss of breathing). This is usually noticeable at birth. The rate of respiration may increase more than three times that of normal (up to 200 breaths per minute), and the apnea may last up to 90 seconds. The rapid breathing occurs most often when affected infants are awake, especially when they are excited. The apnea

happens when the infants are awake or asleep. Such abnormal breathing can cause sudden death or coma and requires that these infants be under intensive care. For unknown reasons, the breathing tends to improve with age, usually within the first year of life.

Muscle movement of the eye is also affected in Joubert syndrome. It is common for the eyes to have a quick, jerky motion of the pupil, known as nystagmus. The retina (the tissue in the back of the eye that receives and transmits visual signals to the brain) may be abnormal. Some individuals (most often males) may have a split in the tissue in the iris of the eye. Each of these problems will affect their vision, and eye surgery may not be beneficial.

The central nervous system problem affects the larger muscles of the body as well, such as those of the arms and legs. Many affected infants will have severe muscle weakness and delays in development. They reach normal developmental milestones, such as sitting or walking, much later than normal. For example, some may learn to sit without support at around 19 to 20 months of age. (Normal is at six to eight months.) Most individuals are not able to take their first steps until age four or older. Their balance and coordination are also affected, which makes walking difficult. Many will have an unsteady gait and find it difficult to climb stairs or run, even as they get older.

Cognitive (mental) delays are also a part of the syndrome, although these manifestations can be variable. Most individuals with Joubert syndrome will have fairly significant learning impairment. Some will have little or no speech. Others are able to learn words and can talk with the aid of speech therapy. They do tend to have pleasant and sociable personalities, but problems in behavior can occur. These problems most often are in temperament, hyperactivity, and aggressiveness.

Careful examination of the face, especially in infancy, shows a characteristic appearance. They tend to have a large head and a prominent forehead. The eyebrows look high and rounded, and the upper eyelids may be droopy (ptosis). Their mouth often remains open and looks oval-shaped. The tongue may protrude and rest on the lower lip, or it may quiver slightly. These are all signs of the underlying brain abnormality and muscle weakness. Occasionally, the ears look low-set on the head. As affected individuals age, these features become less noticeable.

Less common features of the syndrome include minor birth defects of the hands and feet. Some individuals with Joubert syndrome have extra fingers on each hand. The extra finger is usually on the pinky finger side (polydactyly). It may or may not include bone and could

just be a skin tag. Some patients will also have extra toes on their feet.

Diagnosis

On an MRI scan, individuals with Joubert syndrome will show a typical “molar tooth” mark (an abnormality that looks like the cross-section of a molar tooth. This indication as well as evidence of an absent or incomplete cerebellar vermis, muscle weakness, and delays in development are diagnostic signs. There may also be irregular breathing and abnormal eye movements. Most individuals are diagnosed by three years of age.

Treatment and management

During the first year of life, many infants with Joubert syndrome require a respiratory monitor for their irregular breathing. For the physical and mental delays, it becomes necessary to provide special assistance and anticipatory guidance. Speech, physical, and occupational therapy are needed throughout life. Genetic testing for four of the most common gene mutations causing Joubert syndrome is available. In conjunction with genetic counseling, it may be helpful to parents in considering future pregnancies and also to other children of these parents who do not show symptoms of the disorder but may be carriers of the defective gene(s).

Prognosis

The unusual pattern of breathing as newborns, especially the episodes of apnea, can lead to sudden death or coma. A number of individuals with Joubert syndrome have died in the first three years of life. For most individuals, the irregular breathing becomes more consistent after the first year. However, many continue to have apnea and require medical care throughout their lives. Although the true lifespan remains unknown, there are some individuals with Joubert syndrome who are in their 30s.

Clinical trials of new therapies for Joubert syndrome are underway. Participation in a U.S. clinical trial is

voluntary and at no cost to the participant. All clinical trials receiving U.S. government funding, and some supported by private industry, are posted at <https://www.clinicaltrials.gov>. Foreign trials are listed at <https://www.orpha.net>.

Kabuki syndrome

Definition

Kabuki syndrome is a rare disorder characterized by unusual facial features, skeletal abnormalities, and intellectual impairment. Abnormalities in different organ systems can also be present, but they vary from individual to individual. There is no cure for Kabuki syndrome, so treatment focuses on the specific abnormalities, as well as on strategies to improve the overall functioning and quality of life of the affected person.

Description

Kabuki syndrome is a rare disorder characterized by intellectual disability, short stature, unusual facial features, abnormalities of the skeleton, and unusual skin ridge patterns on the fingers, toes, palms of the hands, and soles of the feet. Many other organ systems can be involved in the syndrome, displaying a wide variety of abnormalities, including congenital heart defects, genitourinary anomalies, other facial and visceral abnormalities, and premature breast development in females. Thus, the manifestations of Kabuki syndrome can vary widely among different individuals.

Kabuki syndrome (also known as Niikawa-Kuroki syndrome) was first described in 1980 by Dr. N. Niikawa and Dr. Y. Kuroki of Japan. The disorder received its name from the characteristic long eyelid fissures with eversion of the lower eyelids that is similar to the makeup of actors of Kabuki, a traditional Japanese theatrical form. Kabuki syndrome was originally known as Kabuki makeup syndrome, but the term “makeup” is now often dropped, as it is considered offensive to some families.

Scientific research suggests that Kabuki syndrome may be associated with a change in the genetic material associated with genes *KMT2D* and *KDMA6*.

Genetic profile

Kabuki syndrome is an autosomal dominant syndrome. Studies have shown that an alteration of the *KMT2D* and *KDMA6* genes results in Kabuki syndrome. A review of cases with an alteration of the *KMT2D* gene showed 47% frameshift mutations, 34% nonsense mutations, and 18% pathogenic missense mutations, although variants are also reported. Reports note that 50%–75% of patients with Kabuki syndrome have an alteration of the *KMT2D* gene, while an alteration of the *KDMA6* gene makes up a much smaller percentage. These changes cause a premature stop codon that likely results in the lack of transcription of the entire gene. Located on chromosome 12, *KMT2D* is important in the coding of a protein that is used for spatial and temporal expression of other genes. An alteration in this gene results in a variety of genetic changes related to brain and body development, as seen in the presentation of the signs and symptoms of the disease. Since the finding of this genetic information, an alteration of the *KMT2D* gene denotes the primary Kabuki syndrome and an alteration of the *KDMA6* gene denotes the secondary, type II Kabuki syndrome. Type II Kabuki syndrome shares the same phenotype as Kabuki syndrome, but it is reported to have a dominant pattern of X-linked inheritance.

In almost all cases of Kabuki syndrome, there is no family history of the disease. These cases are thought to represent new genetic changes that occur randomly and with no apparent cause and are termed “sporadic.” However, in several cases the syndrome appears to be inherited from a parent, supporting a role for genetics in the cause of Kabuki syndrome. Scientists hypothesize that an unidentified genetic abnormality that causes Kabuki syndrome is transmitted as an autosomal dominant trait. With an autosomal dominant trait, only one abnormal gene in a gene pair is necessary to display the disease, and an affected individual has a 50% chance of transmitting the gene and the disease to a child.

KEY TERMS

Autosomal dominant—A pattern of genetic inheritance in which only one abnormal gene is needed to display the trait or disease.

Cardinal symptoms—A group of symptoms that define a disorder or disease.

Gastric tube—A tube that is surgically placed through the skin of the abdomen to the stomach so that feeding with nutritional liquid mixtures can be accomplished.

Gastroenterologist—A physician who specializes in disorders of the digestive system.

Kabuki—Traditional Japanese popular drama performed with highly stylized singing and dancing using special makeup and cultural clothing.

Neurologist—A physician who specializes in disorders of the nervous system, including the brain, spine, and nerves.

Demographics

Kabuki syndrome is a rare disorder with an incidence in the Japanese population of about 1 in 32,000 and at least 1 in 86,000 in Australia and New Zealand. The prevalence of the disease may be underestimated, as only a handful of physicians have firsthand experience diagnosing children with Kabuki syndrome. Kabuki syndrome appears to be found equally in males and females. Earlier cases were reported only in Japanese children, but the syndrome is now known to affect other racial and ethnic groups.

Signs and symptoms

The signs and symptoms associated with Kabuki syndrome are divided into cardinal symptoms (i.e., those that are almost always present) and variable symptoms (those that may or may not be present). Cardinal signs and symptoms include typical face, skin-surface abnormalities, skeletal abnormalities, mild to moderate intellectual disability, and short stature.

Diagnosis

The diagnosis of Kabuki syndrome relies on physical exam by a physician familiar with the condition and by radiographic evaluation, such as the use of x-rays or ultrasound to define abnormal or missing structures that are consistent with the criteria for the condition. A person can be diagnosed with Kabuki syndrome if he or she

possesses characteristics consistent with the five different groups of cardinal symptoms.

Although a diagnosis may be made as a newborn, most often the features do not become fully evident until early childhood. Genetic testing via exome sequencing may be available for *KMT2D* and *KDMA6* genes for further diagnosis.

Treatment and management

There is no cure for Kabuki syndrome. Treatment of the syndrome is variable and centers on correcting the different manifestations of the condition and on strategies to improve the overall functioning and quality of life of the affected individual.

For children with heart defects, surgical repair is often necessary. This may take place shortly after birth if the heart abnormality is life threatening, but often physicians will prefer to attempt a repair once the child has grown older and the heart is more mature. For children who experience seizures, lifelong treatment with antiseizure medications is often necessary.

Children with Kabuki syndrome often have difficulties feeding, either because of mouth abnormalities or because of poor digestion. In some cases, a tube that enters into the stomach is surgically placed in the abdomen and specially designed nutritional liquids are administered through the tube directly into the stomach.

People with Kabuki syndrome are at higher risk for a variety of infections, most often involving the ears and the lungs. In cases such as these, antibiotics are given to treat the infection, and occasionally brief hospital stays are necessary. Most children recover from these infections with proper treatment.

Nearly half of people affected by Kabuki syndrome have some degree of hearing loss. In these individuals, formal hearing testing is recommended to determine if they might benefit from a hearing-aid device. A hearing aid is a small mechanical device that sits behind the ear and amplifies sound into the ear of the affected individual. Occasionally, hearing loss in individuals with Kabuki syndrome is severe, approaching total hearing loss. In these cases, early and formal education using American Sign Language as well as involvement with the hearing-impaired community, schools, and enrichment programs is appropriate.

Children with Kabuki syndrome should be seen regularly by a team of healthcare professionals, including a primary care provider, medical geneticist familiar with the condition, gastroenterologist, and neurologist. After growth development is advanced enough (usually late adolescence or early adulthood), consultation with a

QUESTIONS TO ASK YOUR DOCTOR

- Which symptoms of Kabuki syndrome pose the greatest threat to my child's survival and why?
- What prognosis can you suggest for my child, and what factors affect that prognosis?
- Is there any research being conducted on possible treatments or cures for Kabuki syndrome?

reconstructive surgeon may be of use to repair physical abnormalities that are particularly debilitating.

During early development and progressing into young adulthood, children with Kabuki syndrome should be educated and trained in behavioral and mechanical methods to adapt to any disabilities. This program is usually initiated and overseen by a team of healthcare professionals including a pediatrician, physical therapist, and occupational therapist. A counselor specially trained to deal with issues of disabilities in children is often helpful in assessing problem areas and encouraging healthy development of self-esteem. Support groups and community organizations for people with disabilities often prove useful to the affected individuals and their families, and specially equipped enrichment programs should be sought. Furthermore, because many children with Kabuki syndrome have poor speech development, a consultation and regular session with a speech therapist is appropriate.

Prognosis

The abilities of children with Kabuki syndrome vary greatly. Most children with the condition have a mild to moderate intellectual impairment. Some children will be able to follow a regular education curriculum, while others will require adaptations or modifications to their schoolwork. Many older children may learn to read at a functional level.

The prognosis of children with Kabuki syndrome depends on the severity of the symptoms and the extent to which the appropriate treatments are available. Most of the medical issues regarding heart, kidney, or intestinal abnormalities arise early in the child's life and are improved with medical treatment. Since Kabuki syndrome was discovered relatively recently, very little is known regarding the average lifespan of individuals affected with the condition; however, present data on Kabuki syndrome does not point to a shortened lifespan.

Kallmann syndrome

Definition

Kallmann syndrome (KS) is an inherited disorder of hypogonadotropic hypogonadism (HH), delayed puberty, and anosmia (inability to smell).

Description

HH occurs when the body does not produce enough of two important hormones, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), because of a deficiency of gonadotropin-releasing hormone (GnRH). This deficiency results in underdeveloped gonads and often infertility. Anosmia was first described with HH in 1856, but it was not until 1944 that Kallmann reported the inheritance of the two symptoms together in three separate families. Hence, the syndrome of HH with anosmia was designated Kallmann syndrome (KS). KS is also called isolated gonadotropin-releasing hormone deficiency (IGD) with impaired sense of smell and, occasionally, dysplasia olfactogenitalis of De Morsier.

KS is usually detected in adolescence because of failure to undergo puberty. There are multiple types of KS, with multiple inheritance patterns and features, caused by mutations in different genes. The most common features are HH and anosmia, though a wide range of features can be present in an affected person, including a small penis or undescended testicles in males, kidney abnormalities, cleft lip and/or palate, clubfoot, hearing problems, and central nervous system problems such as synkinesia (involuntary movements), eye-movement abnormalities, and visual and hearing defects.

Embryology

Normally, a structure in the brain called the hypothalamus makes GnRH. This hormone acts on the pituitary gland, another nearby structure in the brain, to produce FSH and LH. Both of these hormones travel to the gonads, where they stimulate the development of sperm in men, and eggs in women. FSH is also involved in the release of a single egg from the ovary once per month. HH results when there is an alteration in this pathway that results in inadequate production of LH or FSH. In KS, the hypothalamus is unable to produce GnRH, and thus the production of LH and FSH is not stimulated and does not occur.

The relationship of HH and anosmia can be explained during the development of an embryo. The cells that eventually make GnRH in the hypothalamus are first found in the nasal placode, part of the developing olfactory system (for sense of smell). The GnRH-producing cells must migrate, or move, from the nasal placode up into the brain to the hypothalamus. These cells migrate by following the path of another type of cell called olfactory neurons. Neurons are specialized cells that are found in the nervous system and have long, tail-like structures called axons. The axons of the olfactory neurons grow from the nasal placode up into the developing front of the brain. Once they reach their final destination in the brain, they form the olfactory bulb, the structure in the brain that helps process odors for the sense of smell. The GnRH-producing cells follow the pathway of the olfactory neurons up into the brain to reach the hypothalamus.

In KS, the olfactory neurons are unable to grow into the brain. As a result, the olfactory bulb does not form, resulting in the inability to smell, and the GnRH-producing cells cannot follow the pathway of the axons and do not reach their final destination in the hypothalamus. Hence, no GnRH is made to stimulate the pituitary to make FSH and LH, resulting in no gonad development or HH.

Genetic profile

Most cases of KS are sporadic, meaning that they are caused by new gene mutations rather than mutations inherited from a parent. However, some cases are inherited in an autosomal dominant pattern, an autosomal recessive pattern, or an X-linked recessive pattern. Most cells of the body contain structures called chromosomes. Chromosomes contain genes, which are instructions for all of the proteins necessary for growth, development, and function. There are 46 chromosomes, or 23 pairs of chromosomes, in each cell. The first 22 chromosomes are the same in men and women and are called the autosomes. The last pair, the sex chromosomes, is different in males and females. Men have an X and a Y chromosome (XY). Females have two X chromosomes (XX). All of the genes of the autosomes and the X chromosomes in females come in pairs.

Autosomal dominant inheritance occurs when only one copy of a gene pair is altered or mutated to cause the condition. In autosomal dominant inheritance, the second normal gene copy cannot compensate, or make up for, the altered gene. People with autosomal dominant inheritance have a 50% chance of passing the gene and the condition on to each of their children.

Autosomal recessive inheritance occurs when both copies of a gene are altered or mutated to cause the condition. In autosomal recessive inheritance, the affected person has inherited one altered gene from his or her mother, and the other altered gene from his or her father. Couples who both have one copy of an altered autosomal recessive gene have a 25% risk with each pregnancy of having an affected child.

X-linked recessive inheritance is thought to be the least common form of KS inheritance but is the best understood at the genetic level. With X-linked recessive inheritance, the altered gene that causes the condition is on the X chromosome. Since men have only one copy of the X chromosome, they have only one copy of each gene on the X chromosome. If that one copy is altered, they will have the condition, because they do not have a second copy of the gene to compensate. Women, however, can have one altered copy of the gene and not be affected, as they have a second copy to compensate. In X-linked recessive conditions, women are generally not affected with the condition. Women who are carriers for an X-linked recessive condition have a 50% chance that each of their sons will be affected.

The genes associated with KS are important for certain areas of brain development in the fetus, especially for the formation and movement of olfactory neurons and the migration of nerve cells that produce GnRH. GnRH directs the production of several other hormones that are responsible for prenatal sexual development, for

puberty, and for the function of ovaries in women and testes in men. Therefore, mutations in these genes cause HH and anosmia.

About half of all individuals with KS have a recognizable gene mutation. Mutations in the following genes account for 25% to 30% of KS cases.

- *KAL1* (*ANOS1*), which instructs the body to make a protein called anosmin-1, causes KS type 1 and most cases of X-linked recessive KS. Anosmin-1 is involved in providing the pathway in the brain along which the olfactory axons grow. Anosmin-1 is also found in other parts of the body, possibly explaining some of the other symptoms sometimes observed with KS.
- *FGFR1*, on chromosome 11, encodes fibroblast growth factor receptor 1 and is associated with KS types 2 and 6.
- *PROKR2* causes KS type 3.
- *PROK2* causes KS type 4.

Other KS-associated genes have been identified that interfere with the migration pathway of cells from the olfactory area to the hypothalamus (brain) include *KAL1*, *NELF*, *FGFR1*, *FGF8*, *PROK2*, *PROKR2*, *HS6ST1*, *CHD7*, *WDR11*, and *SEMA3A*. Genes that primarily interfere with the normal secretion of GnRH or its action on the pituitary include *GNRH1*, *KISS1*, *KISS1R*, *TAC3*, and *TACR3*. This clearly is a complicated system, and some of these genes perform more than one function. As only half of all KS individuals have had a specific gene mutation identified, additional KS-associated genes may be identified in the future.

Demographics

Kallmann syndrome is the most frequent cause of HH and affects approximately one in 30,000 males and one in 120,000 females. KS occurs in people of all ethnic backgrounds.

Signs and symptoms

The signs and symptoms of KS can vary among affected individuals even within the same family. The two features most often associated with KS are HH and the inability to smell and failure to initiate puberty. Males can also have a small penis and undescended testicles at birth (testicles remaining in the body rather than dropping down into the scrotal sac). Clubfoot, cleft lip, and/or cleft palate can also be present at birth. Clubfoot occurs when one or both feet are not properly placed on the legs and can appear turned. Cleft lip and/or cleft palate occur when the upper lip and/or the roof of the mouth fail to come together during development. Kidney abnormalities, most often unilateral renal agenesis (one kidney that does not form), are especially common in males with X-linked

KEY TERMS

Anosmia—Impairment or absence of the sense of smell.

Gonadotropin-releasing hormone (GnRH)—The hormone produced by the hypothalamus that stimulates the release of gonadotropins such as luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

Hormone—A chemical messenger produced by the body that is involved in regulating specific bodily functions such as growth, development, and reproduction.

Hypogonadotropic hypogonadism (HH)—Underdevelopment of the gonads due to a deficiency of gonadotropin-releasing hormone.

Hypothalamus—A part of the forebrain that controls heartbeat, body temperature, thirst, hunger, body temperature and pressure, blood sugar levels, and other functions.

Neuron—The fundamental nerve cell that conducts impulses in the brain and nervous system.

Pituitary gland—A small gland at the base of the brain responsible for releasing many hormones, including luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

Puberty—The developmental stage in which the gonads begin to function, and secondary sexual characteristics begin to appear.

Synkinesia—Involuntary movement of a part of the body when another part of the body moves.

recessive KS. Choanal atresia (a blocked pathway from the nose at birth) and structural heart defects have also been seen in KS.

Central nervous system problems can occur. These may include nystagmus (involuntary eye movements), ataxia (involuntary body movements), hearing loss, and problems with vision. Synkinesia is especially common in men with the X-linked recessive form of KS. Some people with KS are also mentally limited. Holoprosencephaly, in which the brain fails to develop in two halves, is also seen in some individuals with KS.

Diagnosis

Individuals with KS might not be diagnosed until they fail to undergo the normal stages of puberty. Hormone testing shows that both LH and FSH are decreased.

QUESTIONS TO ASK YOUR DOCTOR

- How is Kallmann syndrome diagnosed?
- Are there prenatal tests for this genetic disorder?
- If my first child was diagnosed with Kallmann syndrome, what are the chances that future children will also have the disorder?
- Are there at-home treatments to help my child to deal with the worst symptoms of Kallmann syndrome?
- What is my child's prognosis?

Affected individuals often do not realize that they cannot smell. MRI can often detect the absence of the olfactory bulb in the brain. Renal ultrasound can determine whether a kidney is missing.

When an isolated case of KS is diagnosed, evaluation of first-degree family members, such as parents and siblings, should be performed. This should include a detailed family history, measurement of hormone levels, assessment of sense of smell, and renal ultrasound to look for kidney abnormalities. This information may help diagnose previously unrecognized cases of KS. Furthermore, this information may be important for genetic counseling and determining who in the family is at risk for KS.

Molecular genetic testing is available for at least four KS-causing mutations, and carrier testing may be available if the KS-causing mutation or mutations in the family have been identified. Prenatal testing and preimplantation genetic diagnosis are possible if the mutation or mutations are known.

Treatment and management

When a child with KS is born with structural abnormalities such as cleft lip and/or palate, clubfoot, or heart defects, surgery is often necessary to repair the defect. Delayed puberty can be treated with sex hormones—estrogen for females, and testosterone for males. Once puberty is achieved, GnRH or LH and FSH can treat hypogonadism. Treatment is usually successful, and infertility can be reversed. However, a small number of people do not respond to treatment.

Prognosis

For people with the most common features of KS—hypogonadism and the inability to smell—the prognosis is excellent. In most cases, hormone treatment can reverse

the delayed puberty and hypogonadism. For individuals with other symptoms of KS, prognosis depends on the severity of the defects. For example, structural heart defects can be quite complex and sometimes cannot be surgically repaired. No specific treatment is available for those affected by intellectual disability.

Clinical trials for treating Kallmann syndrome, including experimental drug treatments and procedures, are underway. Participation in a U.S. clinical trial is voluntary and at no cost to the participant. All clinical trials receiving U.S. government funding, and some supported by private industry, are posted at <https://www.clinicaltrials.gov>. Foreign trials are listed at <https://www.orpha.net>

Karyomapping

Definition

Karyomapping is a method of preimplantation genetic testing (PGT) for detecting abnormalities in a single gene from a single cell taken from an embryo created by in vitro fertilization (IVF). Because karyomapping

was first used to identify mutations that cause monogenic (single-gene or Mendelian) disorders, it is currently referred to as PGT-M to distinguish it from techniques used to identify abnormalities involving entire chromosomes (PGT-A) or structural rearrangements of the parents' chromosomes (PGT-SR). Karyomapping has, however, been shown to detect some structural abnormalities in parental chromosomes as well as single-gene mutations. The name of the procedure comes from the Greek word for seed or kernel, combined with the English word mapping.

Karyomapping should not be confused with karyotyping, which is the process of taking a photograph of an individual's chromosomes in order to count the number of chromosomes and detect any abnormalities in their number or structure.

Description

History

Karyomapping was made possible by the identification of single nucleotide polymorphisms (SNPs) in the early 2000s. Each SNP represents a difference in a single DNA nucleotide. SNPs are the most common type of genetic variation among humans; there are between four and five million SNPs in a person's genome. Most SNPs have no effect on a person's development or health; however, SNPs that occur within or near a gene may affect that gene's function, and these SNPs can serve as markers of genes associated with genetic diseases.

Other advances in technology and genome analysis that contributed to the development of karyomapping include the introduction of polymerase chain reaction (PCR) as a way to obtain a sufficiently large sample of DNA from a single cell, coupled with improved methods of preserving embryos obtained through assisted reproductive technology (ART). As of 2021, all embryos tested by karyomapping are obtained by hormonal stimulation of the mother's ovaries followed by IVF. The resultant embryos are kept in culture until they have reached the blastocyst stage, usually about eight days after fertilization.

Technique

Karyomapping is done for couples who already know themselves to be at risk of having a child with a monogenic disorder, either because they have already had their DNA tested, have relatives affected by the disorder in question, or have already had a child with the disorder. Karyomapping can be done for autosomal recessive disorders (most often for cystic fibrosis, sickle cell anemia, beta-thalassemia, and spinal muscular atrophy), autosomal dominant disorders (Huntington's disease, myotonic dystrophy, and Charcot-Marie-Tooth

disease), and X-linked diseases (fragile X syndrome, hemophilia A, and Duchenne muscular dystrophy).

Karyomapping begins with obtaining a cheek swab or blood or saliva samples from each of the parents and one or more relatives of the couple who may be affected by the disorder or are carriers of it. If the genetic disorder in question is autosomal recessive, it means that each parent carries the defective gene, and DNA samples must be obtained either from an affected child or from the couple's parents. If the genetic disorder is autosomal dominant, only samples from the affected side of the family are needed; that is, samples are needed from the couple and an affected child, or from a parent affected by the disorder. These samples are then analyzed to obtain the SNP profiles of the four parental chromosomes that carry the gene associated with the disorder. Karyomapping examines the chromosomes at 300,000 different SNPs in order to identify a DNA "fingerprint" unique to the chromosome that carries the defective gene.

The next step involves obtaining embryos through a standard IVF cycle. The mother is given some type of hormonal stimulation to produce eggs, which are then removed from the ovaries through the vagina in a process called follicular aspiration. The eggs are then fertilized outside the mother's body and kept in a culture medium for five-to-nine days until the developing embryos reach the blastocyst stage. A blastocyst, which is 0.1 to 0.2 mm in size, consists of an outer layer of cells called the trophoblast (also called the trophectoderm), which will eventually give rise to the placenta, a fluid-filled inner cavity called the blastocoel, and an inner cell mass that will develop into the fetus.

Each of the blastocysts produced in the IVF cycle can then be tested for the DNA fingerprint that indicates the presence of the defective gene. In karyomapping, only one or two cells are removed from the trophoblast for preimplantation testing; this small biopsy sample will not disturb the developing blastocyst. The biopsy is usually done in the local IVF clinic; the actual karyomapping is carried out in a specialized genetic testing laboratory. The turnaround time for the laboratory work is about a week.

A blastocyst that does not carry the DNA fingerprint indicating the defective gene is assumed to be genetically normal and can then be transferred into the mother's uterus for implantation and further development into a healthy fetus. Other blastocysts that are found to be healthy can be frozen for use in a later pregnancy if desired.

Regulation

Karyomapping is regulated in Europe as of 2021 although it (or any other form of preimplantation genetic testing) is not regulated in the United States. The reason for this difference is that countries like France and the

KEY TERMS

Autosome—Any chromosome that is not a sex chromosome. The human genome has 22 pairs of autosomes.

Blastocyst—The phase of human embryonic development that occurs about 5–9 days after fertilization. The blastocyst consists of an outer layer of cells; an inner mass of cells; and a fluid-filled cavity.

Carrier—In genetics, a person who has a genetic mutation associated with a disease and is capable of passing it on. A carrier may or may not display the symptoms of the disease.

Chromosome abnormalities—A general term for abnormalities in either the number or the structure of chromosomes.

Genome—The total amount of genetic information within an organism's chromosomes, including its genes and DNA sequences.

Germline—The population of a complex organism's cells that pass on genetic information to offspring. Germline cells include eggs, sperm, and fertilized eggs.

In vitro fertilization (IVF)—A form of assisted reproduction technology in which a human ovum (egg) is combined with sperm outside the body in a laboratory container ("in vitro" means "in glass").

Karyotype—The complete set of chromosomes in a species or individual organism. The term can also refer to the laboratory technique used to produce an image of an individual's chromosomes.

Mendelian disease—A disease caused by a single mutated gene; also called a single-gene disease.

Monogenic disease—Another term for a single-gene disorder.

Mosaicism—A condition in which two or more genetically different sets of cells occur in the same individual.

Nucleotide—A building block of a nucleic acid (DNA or RNA), consisting of a sugar molecule, a phosphate group, and one of the nitrogen-containing bases (adenine, cytosine, guanine, and thymine in DNA; adenine, cytosine, guanine, and uracil in RNA).

Polymerase chain reaction (PCR)—A method for obtaining a sufficient sample of DNA to analyze by amplifying or making copies of a small segment of DNA through a series of cycles of temperature changes. PCR is sometimes called molecular photocopying.

Preimplantation genetic testing (PGT)—A screening test performed on embryos created by IVF to analyze the genetics of each embryo prior to transfer into the intended mother's uterus.

Single nucleotide polymorphism (SNP)—A germline substitution of a single nucleotide (any of a group of molecules that form the building blocks of DNA or RNA) at a specific position in a person's genome.

United Kingdom have either statutory bodies (the Human Fertilisation and Embryology Authority (HFEA) in the UK) or nationwide public health codes (as in France). The HFEA permits preimplantation testing for over 400 different genetic disorders, while the French Agence de la Biomédecine is more restrictive than its British counterpart.

By contrast, the United States has no government-funded health care program on the national level, nor is IVF (which is a prerequisite for karyomapping) covered by federal programs like Medicare or Medicaid. The exception is Veterans Affairs (VA) coverage of IVF for veterans who lost their fertility as a result of a service-related injury. As of 2021, while 17 states (Arkansas, California, Connecticut, Delaware, Hawaii, Illinois, Louisiana, Maryland, Massachusetts, Montana, New Hampshire, New Jersey, New York, Ohio, Rhode Island, Texas and West Virginia) require health insurance

companies to cover or offer IVF as well as other fertility treatments. Other states have no such provisions.

Another problem is that the United States has no regulatory body responsible for the clinical practice of karyomapping and other forms of PGT. While the Food and Drug Administration (FDA) is tasked with ensuring the effectiveness and safety of drugs and medical devices, it does not regulate how and when they should be used. The Centers for Disease Control and Prevention (CDC) collects data each year on fertility treatments, but its work is limited to data collection and reporting. Federal regulation of PGT would require either the creation of a new agency or assignment of oversight to an existing agency.

Limitations

Karyomapping has several limitations. One is that it is most useful in identifying monogenic disorders,

QUESTIONS TO ASK YOUR DOCTOR

- Have you ever recommended karyomapping to a patient concerned about a single-gene disorder in a planned pregnancy?
- Why do you think that IVF and karyomapping are so expensive?
- Do you think that the FDA or another federal agency should regulate karyomapping in the United States?
- What do you consider the limitations and risks of karyomapping as a diagnostic technique?

although in a few cases it has been found effective in identifying two monogenic disorders in the same family and identifying some forms of structural rearrangement of chromosomes. It cannot, however, be reliably used to screen for abnormalities in the number of chromosome copies, or for simultaneous screening of a panel of single-gene genetic disorders. Karyomapping is also unable to reliably identify mosaicism (the presence of two or more distinct cell lines in the same embryo) because it samples so few cells, and it is known that embryos with mosaicism are less likely to implant successfully in the mother's uterus.

Another limitation is that karyomapping employs PCR amplification of the DNA found in only one or two cells taken from the trophoblast of the blastocyst. While karyomapping is about 95% (some sources say 97%) accurate in identifying healthy embryos for transfer, it cannot absolutely exclude the possibility of misdiagnosis. As a result, the American College of Obstetricians and Gynecologists (ACOG) recommends that karyomapping should be followed up with amniocentesis or chorionic villus sampling of the resulting pregnancy.

The most important limitation for many couples is the cost of the procedure. As karyomapping requires an IVF cycle, the cost of ovarian stimulation, egg retrieval, fertilization, biopsy of trophoblast cells from the blastocyst, freezing of the embryos, the actual karyomapping, and embryo transfer runs as high as \$16,000 as of 2021, with the cost of medications extra. The embryo biopsy charges alone run between \$1000 and \$2200.

Research

There are no clinical trials of karyomapping registered with the NIH as of mid-2021.

Karyotype

Definition

A karyotype is the arrangement of chromosomes in their matched (homologous) pairs. Human chromosomes are arranged and numbered according to the International System for Human Cytogenetic Nomenclature (ISCN). Karyotype can refer to either the composition of the chromosomes in a cell of an individual or species or to a diagram or photograph of the chromosomes arranged in their pairs.

Description

The normal human karyotype consists of 23 pairs of chromosomes. There are 22 pairs of autosomes—the chromosomes other than the X and Y sex chromosomes. Females normally have two X chromosomes, and males have one X chromosome and one Y chromosome. The karyotype reveals the number of chromosomes; their arrangement, size, and shape; and any structural abnormalities.

Karyotyping is used to examine the chromosomes in cells to identify genetic disorders caused by chromosome abnormalities. Chromosome preparations can be made

KEY TERMS

Acrocentric—A centromere positioned at the top end of a chromosome.

Autosomes—The chromosomes other than the X and Y sex chromosomes.

Banding—Striped patterns that are visible on stained chromosomes and that are distinctive for each chromosome.

Centromere—A constricted region of a chromosome that is involved in cell division and that divides the chromosome into the long arm (q) and the short arm (p).

Chromosomal microarray (CMA)—A more sensitive method for detecting chromosome abnormalities than conventional karyotyping.

Homologous chromosomes—The two members of a chromosome pair, one inherited from each parent.

Metacentric—A centromere in the middle of the chromosome.

Metaphase—The stage in cell division when the chromosomes are arranged along an equatorial plane.

Satellites—Small segments of genetic material at the tips of the short arms of chromosomes 13, 14, 15, 21, and 22.

Submetacentric—A centromere located between the center and the top of the chromosome.

Translocation—The transfer of material in a chromosome to a different position, especially to a nonhomologous chromosome; translocations may be balanced, in which no genetic material is lost or gained, or unbalanced with the loss or gain of genetic material.

from almost any dividing cells, including blood cells, skin cells, amniotic fluid cells (the fluid surrounding an unborn baby), placental tissue or chorionic villi (tissue that forms the placenta and can be used in prenatal diagnosis), bone marrow, or biopsied tissue. Karyotypes are used to identify:

- problems in a developing fetus
- causes of multiple miscarriages or stillbirths
- causes of multiple birth defects
- causes of unusual features or developmental delays in infants and children

Karyotype showing three copies of chromosome 21, which indicates Down syndrome. (Clark Heath/Centers for Disease Control and Prevention)

- chromosome disorders such as Down syndrome, Klinefelter syndrome, Turner syndrome, and trisomy 18
- ambiguous genitalia (a mixture of male and female genitals)
- a “Philadelphia chromosome,” which is usually present in chronic myelogenous leukemia cells
- chromosome abnormalities in other leukemias and cancers

To prepare a karyotype, the cell samples are grown in the laboratory in a dish or tube with rich medium to promote cell division. Chromosomes are individually distinguishable only during a certain stage of cell division known as metaphase. Therefore, a karyotype is made during metaphase and referred to as a metaphase spread. At metaphase, the chromosomes are removed from the cell nucleus, mounted on a slide, stained, and examined and photographed under a microscope. The photographs are then arranged into a karyotype.

Karyotype construction

For the construction of the karyotype, the chromosomes are numbered 1 through 22 from longest to shortest. The 23rd pair is the sex chromosomes and is placed on the karyotype after the 22nd pair. The chromosomes can be separated into groups, based on their length and

the position of the centromere. The centromere is a constricted region of the chromosome that is involved in cell division and is used to define the long arm (q) and the short arm (p) of each chromosome. Group A consists of chromosome pairs 1, 2, and 3. These are the longest chromosomes, and their centromeres are located at the center of each chromosome (metacentric). Group B consists of chromosome pairs 4 and 5. These are long, but their centromeres lie toward the top of each chromosome (submetacentric). Group C consists of chromosome pairs 6, 7, 8, 9, 10, 11, and 12 and the X chromosome(s). These are of medium length, and their centromeres are located either in the middle or toward the top of the chromosome. Group D consists of chromosome pairs 13, 14, and 15. These are of medium length, and their centromeres lie at the top of the chromosome (acrocentric). Additionally, D group chromosomes have satellites (small fragments of genetic material at the tip of the short arm). Group E consists of chromosome pairs 16, 17, and 18. These are relatively short chromosomes, and their centromeres are located in the center or toward the top of the chromosome. Group F consists of chromosomes 19 and 20. These are short chromosomes with centromeres located in the center. Lastly, group G consists of chromosome pairs 21, 22, and the Y chromosome. These are short chromosomes with their centromeres at the top.

QUESTIONS TO ASK YOUR DOCTOR

- Will my cells be karyotyped?
- What cells will be used for karyotyping?
- How will the cells be obtained?
- What method will be used for karyotyping?
- What information will my karyotype provide?

Chromosome pairs 21 and 22 have satellites. The Y chromosome does not have satellites.

Chromosomes in a metaphase preparation are stained to reveal patterns of light and dark stripes called bands. Staining the chromosomes with Giemsa dye is referred to as “G-banding.” Each numbered chromosome is unique in its banding pattern, although there may be slight normal familial variations. Banding makes it easier to identify the chromosomes and visualize any differences or abnormalities. For example, banding makes it much easier to see if a chromosome is missing a piece, if two chromosomes are attached to each other, or if a piece of one chromosome is joined to another chromosome (a translocation).

Chromosome complements are described by ISCN formulas. The basic formula for describing a karyotype is the total number of chromosomes followed by the sex chromosome complement. Thus, a typical female karyotype is written as 46,XX, and a typical male karyotype is written as 46,XY.

Formulas for abnormal karyotypes

Common formulas for abnormal karyotypes are as follows:

- A plus or minus sign before a chromosome number indicates that an entire chromosome is extra or missing. Therefore, the total number of chromosomes will be more or less than 46. For example, Down syndrome is caused by an extra chromosome 21. The karyotype of a male with Down syndrome is 47,XY,+21.
- Chromosomes may have extra or missing regions of the short arm (p) or long arm (q). For example, Wolf-Hirschhorn syndrome is caused by a missing part of the end of the short arm of chromosome 4. The karyotype of a female with this syndrome is 46,XX,del(4)(p16). The “del” means “deletion,” (4) indicates that chromosome 4 is affected, and (p16) indicates the missing region of the short arm.
- There are many types of balanced and unbalanced translocations. Balanced translocations are exchanges of

regions between two different chromosomes without a gain or loss of genetic material. A Robertsonian translocation occurs when two entire acrocentric chromosomes are attached. A common example is a translocation involving chromosomes 13 and 14. A male with a balanced Robertsonian translocation of chromosomes 13 and 14 has the karyotype 45,XY,der(13;14). Thus, there are only individual chromosomes. The “der” stands for derivative, since the new 13;14 chromosome is considered a derivative.

Newer methods

High-resolution chromosome studies are performed with chromosomes from cells in which cell division has been stopped at an earlier stage, called pro-metaphase. These chromosomes appear longer, and 700–1,200 bands can be seen, compared with the 300–600 bands that are visible with routine metaphase banding. High-resolution karyotyping allows for a more detailed analysis of chromosome structure.

A chromosomal microarray (CMA) is much more sensitive than traditional karyotyping. There are various CMA methods that can be applied to all of the chromosome, to a specific chromosome, or to a specific region of a chromosome. CMA can detect losses or gains of genetic material at single-gene resolution, known as copy number variations. Fluorescent in situ hybridization (FISH) is another technique that can detect small changes, such as deletions, in chromosomes.

Keppen-Lubinsky syndrome

Definition

Keppen-Lubinsky syndrome, often referred to by its acronym (KPLBS) or as Lubinsky syndrome, is a rare autosomal dominant heterozygous genetic disorder. The first case of KPLBS was reported in 2001; therefore, research on it is limited. Research as of 2015 showed that the gene mutation associated with KPLBS leads to a severe impairment of the functioning of the potassium channel the gene codes for, classifying the mutation as a channelopathy. The result of this mutation in the human body leads to severe developmental delay, a dysmorphic appearance, and cognitive disability.

Description

KPLBS is a genetic disorder that directly mutates the *KCNJ6* gene that encodes an integral membrane protein and the inward-rectifier potassium channel. The encoded integral membrane protein is a cellular membrane protein that regulates the amount of potassium that goes in and out of a cell. This is very important for the overall function of the cell. The balance between intracellular and extracellular potassium, for example, is necessary for the regulation of heart rate and the activity of part of the nervous system.

In addition to altering the function of the integral membrane protein structure, the KPLBS mutation also affects the inward-rectifier potassium channel, which plays a role in the regulation of potassium into the cell more so than out of the cell. When this intra-extracellular balance of potassium is altered, many functions of the cell can become either overactive or underactive, depending on the interruptions resulting from the

Nondisjunction, failure of paired chromosomes to separate, can result at different stages of meiosis or mitosis. When nondisjunction occurs in the first (A) or second (B) phase of meiosis the resulting karyotype will be 47,XXY. If the chromosomes fail to separate during mitosis (C) a mosaic karyotype (46,XY/47,XXY) will result. (Gale)

imbalance. This includes a change in the sodium-potassium pump, which plays a major role in the conductivity of both afferent and efferent nerve cells. Researchers have suggested that this alteration of the ratio of sodium to potassium that occurs when the inward-rectifier potassium channels are not working correctly may cause cell death due to the influx of sodium.

Inward-rectifier potassium channels are found throughout the human body in cells including, but not limited to, the following:

- blood cells
- osteoclasts
- endothelial cells
- glial cells
- epithelial cells
- oocytes

The role of potassium in these cells is to mediate the passive and active electrical properties of the cells' signaling, and it may link cellular metabolic state and membrane excitability in vivo as well. When these processes are not functioning correctly, the cell they correlate to will not be able to do its encoded job, leading to the overall dysfunction of the human body as seen in KPLBS. Studies of these channels suggest the importance of potassium channels in differentiation of cells in the embryonic stage, particularly adipocytes. The alteration of differentiation of embryonic adipocytes is suggested to be the underlying reason for the generalized lipodystrophy seen in all three of the cases of KPLBS reported as of 2015.

Genetic profile

KPLBS is an autosomal dominant heterozygous *de novo* mutation in the *KCNJ6* gene located on chromosome 21q22. This also maps to the Down syndrome critical region between *DIRK1A* and *DSCR4*, which is indicative of the resulting mental impairment seen in cases of KPLBS in addition to the musculoskeletal abnormalities. Studies have shown two patterns of mutations of this particular gene that lead to the syndrome. By sequencing exomes of three unrelated individuals diagnosed with KPLBS, the study by Masotti et al. (2015) found that two individuals shared an in-frame heterozygous deletion of three nucleotides, leading to the loss of one amino acid the three nucleotides code for. The third individual was heterozygous for a missense mutation, in which an amino acid change from glycine to serine occurs. This missense of one amino acid for another also changes the nucleotide the triplet codon is meant to code for and results in the overall impairment of the gene. All three cases outlined caused the mutation of the gene

KEY TERMS

Channelopathy—A disorder of channels.

De novo—An alteration in a gene that is present for the first time in one family member as a result of a mutation in a germ cell (egg or sperm) of one of the parents or in the fertilized egg itself.

Lipodystrophy—A medical condition characterized by abnormal or degenerative conditions of the body's adipose tissue.

Microcephaly—A condition of abnormal smallness of the head usually associated with mental defects.

Philtrum—The vertical groove on the median line of the upper lip.

Tetraparesis—Muscle weakness affecting all four limbs.

coding for the inwardly rectifying potassium channel and, due to the heterogeneous nature of this mutation, both genes that coded for the channel were mutated.

Demographics

The Office of Rare Diseases, the National Institutes of Health, and Orphanet, a consortium of European partners, have classified KPLBS as a rare disease, based on their individual parameters. Studies note that as few as three male children have been diagnosed with this syndrome. Of the children, the first was the second child of parents with an American and Hispanic background, the second was the third child of parents with Italian backgrounds, and the third was the second child of Jewish parents with Yemenite backgrounds.

Signs and symptoms

Inspection of a child born with KPLBS will reveal normal growth parameters at birth followed by failure to thrive and poor postnatal growth. After infancy, signs and symptoms of KPLBS are seen more so in the facial features than in the rest of the body. A highly arched superior palate leads to a short philtrum, a tented upper lip, a smaller jaw, and a mouth in the open position. A change in orbital structure causes large, prominent eyes. Generalized lipodystrophy causes a decrease in fat cells in the facial region, causing a hypoplastic nose and giving the face an overall aged appearance from wrinkled skin typically in the forehead and the chin, tightly adhered facial skin, and mask-like facies. Neurological signs and symptoms include, but are not limited to, intellectual disability, decreased intelligence and cognitive function,

QUESTIONS TO ASK YOUR DOCTOR

- How often should my child be monitored for growth or intellectual disability?
- What treatments are available to us for improving my child's quality of life?
- Will the changes in my child's facial features alter the food he or she can eat?
- Are there any support groups established for us to join?

hypertonia/hyperreflexia, and spastic tetraparesis. Other signs and symptoms include respiratory dysfunction, scoliosis, and possible seizures.

Diagnosis

Diagnosis of KPLBS is highly correlated with the signs and symptoms of the mutation seen upon physical and radiological examination of the patient. Neurological examination, brain MRI, and cognitive function tests are also instrumental in the diagnosis of KPLBS. Specific diagnosis can be made via exome sequencing and confirmed by Sanger sequencing. Laboratory tests are typically negative.

Treatment and management

Although there are minimal studies outlining treatment specifically for KPLBS, there have been some animal studies performed for the opioid treatment of pain related to the *KCNJ6* gene. Treatment and management of certain signs and symptoms such as scoliosis, seizures, and spasticity may be provided for a person diagnosed with this syndrome. These may include cognitive therapy, occupational or physical therapy, and pain management. Genetic counseling is recommended for parents considering future offspring following a diagnosis of a child with KPLBS.

Treatment and management of the symptoms associated with the syndrome are more available than treatment for the gene mutation itself. The treatment of life-threatening symptoms of the syndrome, such as respiratory dysfunction, seizures, and changes in structure affecting nutritional status, have a higher priority than non-life-threatening symptoms such as scoliosis, hypertonia, hyperreflexia, and tetraparesis. Cases reported over the last 15 years have shown children being treated with tracheostomy and ventilation for respiratory dysfunction,

percutaneous endoscopic gastrostomy for nutritional deficiencies, and tendon release surgeries for spasticity.

Prognosis

Due to the limited cases of KPLBS in adulthood, the prognosis of this genetic disorder was unknown as of 2015.

Klinefelter syndrome

Definition

Klinefelter syndrome is a chromosome disorder in males. People with this condition are born with at least one extra X chromosome.

Description

Klinefelter syndrome is a condition where one or more extra X chromosomes are present in a male. Boys with this condition appear normal at birth. They enter puberty normally, but by mid-puberty have low levels of testosterone causing small testicles and the inability to make sperm. Affected males may also have learning disabilities and behavior problems such as shyness and

KEY TERMS

Chromosome—A microscopic thread-like structure found within each cell of the body, consisting of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Gonadotrophin—Hormones that stimulate the ovary and testicles.

Testosterone—Hormone produced in the testicles that is involved in male secondary sex characteristics.

immaturity and are at an increased risk for certain health problems.

Genetic profile

Chromosomes are found in the cells in the body. Chromosomes contain genes, structures that tell the body how to grow and develop. Chromosomes are responsible for passing on hereditary traits from parents to child. Chromosomes also determine whether the child will be male or female. Normally, a person has a total of 46 chromosomes in each cell, two of which are responsible for determining that individual's sex. These two sex chromosomes are called X and Y. The combination of these two types of chromosomes determines the sex of a child. Females have two X chromosomes (the XX combination); males have one X and one Y chromosome (the XY combination).

In Klinefelter syndrome, a problem very early in development results in an abnormal number of chromosomes. Most commonly, a male with Klinefelter syndrome will be born with 47 chromosomes in each cell, rather than the normal number of 46. The extra chromosome is an X chromosome. This means that rather than having the normal XY combination, the male has an XXY combination. Because people with Klinefelter syndrome have a Y chromosome, they are all male.

Approximately one-third of all males with Klinefelter syndrome have other chromosome changes involving an extra X chromosome. Mosaic Klinefelter syndrome occurs when some of the cells in the body have an extra X chromosome and the others have normal male chromosomes. These males can have the same or milder symptoms than non-mosaic Klinefelter syndrome. Males with more than one additional extra X chromosome, such as

48,XXXY, are usually more severely affected than males with 47,XXY.

Klinefelter syndrome is not considered an inherited condition. The risk of Klinefelter syndrome reoccurring in another pregnancy is not increased above the general population risk.

Demographics

Klinefelter syndrome is one of the most common chromosomal abnormalities. About one in every 500 to 1,000 males is born with this disorder. Approximately 3% of the infertile male population has Klinefelter syndrome.

Signs and symptoms

The symptoms of Klinefelter syndrome are variable, and not every affected person will have all of the features of the condition. Males with Klinefelter syndrome appear normal at birth and have normal male genitalia. From childhood, males with Klinefelter syndrome are taller than average with long limbs. Approximately 20%–50% have a mild intention tremor, an uncontrolled shaking. Many males with Klinefelter syndrome have poor upper body strength and can be clumsy. Klinefelter syndrome does not cause homosexuality. Approximately one-third of males with Klinefelter syndrome have breast growth, some requiring breast reduction surgery.

Most boys enter puberty normally, though some can be delayed. The Leydig cells in the testicles usually produce testosterone. With Klinefelter syndrome, the Leydig cells fail to work properly, causing the testosterone production to slow. By mid-puberty, testosterone production is decreased to approximately half of normal. This can lead to decreased facial and pubic hair growth. The decreased testosterone also causes an increase in two other hormones, follicle stimulating hormone (FSH) and luteinizing hormone (LH). Normally, FSH and LH help the immature sperm cells grow and develop. In Klinefelter syndrome, there are few or no sperm cells. The increased amount of FSH and LH causes hyalinization and fibrosis, the growth of excess fibrous tissue, in the seminiferous tubules, where the sperm are normally located. As a result, the testicles appear smaller and firmer than normal. With rare exception, men with Klinefelter syndrome are infertile because they cannot make sperm.

While it was once believed that all boys with Klinefelter syndrome were intellectually disabled, doctors now know that the disorder can exist without intellectual disability. However, children with Klinefelter syndrome frequently have difficulty with language, including learning to speak, read, and write. Approximately 50% of males with Klinefelter syndrome are dyslexic.

QUESTIONS TO ASK YOUR DOCTOR

- Why does Klinefelter syndrome affect only males?
- Can Klinefelter syndrome be diagnosed by prenatal tests?
- What information can a genetic counselor provide our family about Klinefelter syndrome?
- Will my son be able to live a normal life if he has been diagnosed with Klinefelter syndrome?

Some people with Klinefelter syndrome have difficulty with social skills and tend to be more shy, anxious, or immature than their peers. They can also have poor judgment and do not handle stressful situations well. As a result, they often do not feel comfortable in large social gatherings. Some people with Klinefelter syndrome can also have anxiety, nervousness, and/or depression.

The greater the number of X chromosomes present, the greater the disability. Boys with several extra X chromosomes have distinctive facial features, more severe intellectual disability, deformities of bony structures, and even more disordered development of male features.

Diagnosis

Diagnosis of Klinefelter syndrome is made by examining chromosomes for evidence of more than one X chromosome present in a male. This can be done in pregnancy with prenatal testing such as a chorionic villus sampling or amniocentesis. Chorionic villus sampling is a procedure done early in pregnancy (approximately 10–12 weeks) to obtain a small sample of the placenta for testing. An amniocentesis is done further along in pregnancy (from approximately 16–18 weeks) to obtain a sample of fluid surrounding the baby for testing. Both procedures have a risk of miscarriage. Usually these procedures are done for a reason other than diagnosing Klinefelter syndrome. For example, a prenatal diagnostic procedure may be done on an older woman to determine if her baby has Down syndrome. If the diagnosis of Klinefelter syndrome is suspected in a young boy or adult male, chromosome testing can also be on a small blood or skin sample after birth.

Treatment and management

There is no treatment available to change chromosomal makeup. Children with Klinefelter syndrome may benefit from a speech therapist for speech problems or other educational intervention for learning disabilities.

Testosterone injections started around the time of puberty may help to produce more normal development including more muscle mass, hair growth, and increased sex drive. Testosterone supplementation will not increase testicular size, decrease breast growth, or correct infertility.

Prognosis

While many men with Klinefelter syndrome go on to live normal lives, nearly 100% of these men will be sterile (unable to produce a child). However, a few men with Klinefelter syndrome have fathered a child through the use of assisted fertility services. Males with Klinefelter syndrome have an increased risk of several conditions such as osteoporosis, autoimmune disorders such as lupus and arthritis, diabetes, and both breast and germ cell tumors.

Klippel-Feil syndrome

Definition

Individuals with Klippel-Feil syndrome (KFS), also called Klippel-Feil sequence, were originally described as having a classic triad of webbed neck (very short

neck), low hairline, and decreased flexibility of the neck. More commonly, KFS features include abnormal joining or fusion of two or more vertebrae (bones) of the cervical spine (neck bones).

Description

KFS is characterized by the extensive fusion of multiple cervical vertebrae (the uppermost bones of the spine). There may be complete fusion or multiple irregular bony segments in the bones of the upper back (cervical and often upper thoracic spine). Premature and extensive arthritis and osseous (bony) spurring affecting the joints of the spine (facet joints) are common in individuals with KFS.

There are three morphologic classifications of KFS.

- Type 1 exhibits fusion of the lower skull (head) and the first bone of the spine (the first cervical vertebrae [C1]). The second and third spinal bones (cervical vertebrae C2 and C3) are also usually fused together in type 1. The normal cervical spine has seven bones or vertebrae. Normally half of the ability of humans to bend their heads forward (flexion) and backward (extension) occurs in the joints between the base of the skull and the uppermost spinal bone. The other half of the motions of flexion and extension occur in the rest of the upper spine. Therefore, the danger is due to the excessive motion of the neck between the joints that are fused.
- Type 2 has fusion of bones (vertebrae) below the second cervical bone (C2). Type 2 also has an abnormal skull and upper spinal bone connection.
- Type 3 has an open space between two fused segments of spinal bones.

Genetic profile

As of 2015, genetic mutations in *GDF6*, *GDF3*, and *MEOX1* genes had been found to cause KFS. A 2008 study reported mutations at the *GDF6* gene locus in some familial and sporadic cases of KFS. The *GDF6* gene encodes a member of the bone morphogenetic protein (BMP) family and another family of secreted signaling molecules. It is required for normal formation of some bones and joints in the limbs, skull, and axial skeleton. Mutations in this gene are believed to play a role in the development of KFS signs and symptoms.

Demographics

As of 2015, it was estimated that KFS occurred in 1 in 40,000 to 42,000 newborns around the world. The incidence rate of KFS seems to be slightly higher in females. There have been some reports of KFS being more common among infants born with fetal alcohol

KEY TERMS

Degenerative disc disease—Narrowing of the disc space between the spinal bones (vertebrae).

Fetal alcohol syndrome—Syndrome characterized by distinct facial features and varying mental retardation in an infant due to impaired brain development resulting from the mother's consumption of alcohol during pregnancy.

Hypoplasia—Incomplete or underdevelopment of a tissue or organ.

Microtia—Small or underdeveloped ears.

Ossicles—Any of the three bones of the middle ear, including the malleus, incus, and stapes.

Radiculopathy—A bulging of disc material often irritating nearby nerve structures resulting in pain and neurologic symptoms; a clinical situation in which the radicular nerves (nerve roots) are inflamed or compressed. This compression by the bulging disc is referred to as a radiculopathy. This problem tends to occur most commonly in the neck (cervical spine) and low back (lumbar spine).

Scoliosis—An abnormal, side-to-side curvature of the spine.

Torticollis—Twisting of the neck to one side that results in abnormal carriage of the head and is usually caused by muscle spasms. Also called wry neck.

syndrome (FAS) because FAS affects bone development of the fetus.

Signs and symptoms

The first clinical signs are the classic triad of webbed neck, low hairline, and decreased flexibility of the neck. However, the presence of abnormalities of the cervical spine found with x-rays is the hallmark diagnosis. Other signs and symptoms may be found, but vary from person to person.

Some patients may exhibit wry neck or torticollis, which is a twisting of the neck to one side that results in abnormal carriage of the head. The individual may have differences between the two sides of his face, known as facial asymmetry. Patients may also have scoliosis (abnormal curves of the spine).

A variety of miscellaneous abnormalities may clinically manifest themselves in KFS. Deafness occurs in about 30% of the cases. Ear abnormalities such as very small ear lobes (microtia), or deformed bones within the

ear (ossicles), may be present. They may even have a small or absent internal ear.

Abnormalities of the blood vessels such as a missing radial artery in the forearm may decrease the size of the thumbs (thenar hypoplasia). Anomalies of the right subclavian artery (artery under the clavicle or collar bone) have been reported as well as higher incidences of artery anomalies of the upper neck (cervical vertebrae). Anomalies of the genital areas and urinary system are also common.

Individuals diagnosed with KFS frequently have problems with cervical nerves and nerves that go from the neck to the arms and hands. Individuals can have pain that starts in their neck and travels into the arms if the nerve roots coming off of the spinal cord are irritated or pinched.

Diagnosis

KFS is usually diagnosed in early childhood or adolescence. Observing the clinical signs of having the classic triad of webbed neck, low hairline, and limited cervical ranges of motion initiates the diagnosis. When further testing is done, such as x-ray, the diagnosis is confirmed by the fusion of multiple cervical vertebrae.

Treatment and management

If the individual has a very mild case of KFS, then the person can lead a normal life with only minor restrictions. These restrictions, such as avoiding contact sports that would place the neck at risk, are necessary because of the instability of the cervical spine. This is due to the increased motion between the fused cervical vertebrae.

Symptoms, such as pain, that occur with the arthritis and degeneration of the joints may also result. The individuals should be treated with pain medication and possible cervical traction. If neurological symptoms occur, the treatment of choice is fusion of the symptomatic area. However, due to the severe consequences of not having the preventive surgery, surgery is still the treatment most performed.

Prognosis

There have been reports of death following minor trauma because of injuries to the spinal cord in the cervical spine. Most commonly, individuals with Klippel-Feil will develop pain. Some diseases are acquired or occur because of the increased motion of the vertebrae. Degenerative disc disease, or destruction of the cushion-like disc between the vertebrae, is also very common and affects the entire lower cervical spine. Spondylotic osteophytes, or bone spurs in the spine, form as a result of this degeneration. This laying down of new bone may lead to narrowing of the canal through which the spinal cord travels (spinal stenosis).

Because of the instability of the spinal cord, surgery may prevent a dangerous and fatal accident. Pain that originates in the neck and travels into the arms (radiculopathy) is common near the sites of the surgical fusion of vertebrae. One study found that 25% of the individuals who had surgery would have had neurological problems within ten years, therefore requiring additional surgery.

Jason S. Schliesser, DC

Klippel-Trenaunay-Weber syndrome

Definition

Klippel-Trenaunay-Weber syndrome (KTWS) is most often defined by the presence of three classic characteristics: vascular abnormalities, prominent varicose veins or darkened skin patches, and limb enlargement.

Description

KTWS was first described by Drs. Klippel and Trenaunay in 1900. The condition is also known by the names Klippel-Trenaunay syndrome (KTS) and angioosteohypertrophy syndrome.

Vascular abnormalities in KTWS may involve the capillary, venous, arterial, and lymphatic systems. Limb enlargement resulting in asymmetry of the limbs is quite common. This usually affects the lower limbs, but occasionally the upper limbs as well. Vein enlargement and varicose veins are also typically a part of KTWS. Other occasional abnormalities in KTWS may involve the fingers and toes, other skin changes, glaucoma, mental delays, seizures, and blood platelet problems.

Genetic profile

In most cases, KTWS occurs by chance alone. There is usually no family history and very little chance of the condition occurring again, even to the same parents. In 2004, researchers reported that abnormalities in the *VG5Q* gene on chromosome 5 were found to cause a susceptibility to KTWS. *VG5Q* is a gene known to be important for blood vessel development, so abnormalities within it might naturally lead to some symptoms of KTWS.

A few families with multiple people who may have KTWS have been noted. One study described a family with three people who were suspected to have KTWS, in three separate generations. Each person had different symptoms seen in KTWS. This family history suggests autosomal dominant inheritance in rare cases of KTWS. In dominant inheritance, an affected individual has a 50% chance of having an affected child with KTWS, regardless of that child's gender. It is also common to see families with histories of the condition in this type of inheritance pattern.

Demographics

KTWS is a relatively uncommon condition that is found worldwide, affecting males and females equally. Additionally, it appears to affect people of all ages, though the average age that children may come for medical care is four years.

Signs and symptoms

Vascular abnormalities

Problems may occur as a result of an abnormal communication between a group of blood vessels and the skin. An abnormal grouping of blood vessels may reach the skin, causing the appearance of a large hemangioma on the skin. Additionally, the blood vessel walls may enlarge or swell, causing large, blood-filled spaces within the

body. Internal bleeding can be a serious complication in some cases. There may also be swelling or masses of tissue from problems in the lymphatic system. These may disturb neighboring tissues and internal organs.

Veins and arteries may join abnormally, which can cause an improper flow of blood between the body's vein and artery systems. The deep veins can be incorrectly developed, sometimes being smaller than usual or even duplicated. Ultimately, this can disrupt the proper circulation of blood between various parts of the body.

Varicose veins are common in KTWS. People may have prominent veins that involve their feet or entire legs.

The lymphatic system, meant to help blood and fluid circulate, can be problematic in those with KTWS. Lymphatic fluid can collect abnormally, causing an enlargement and swelling of surrounding tissues. Smaller swellings can occur in various parts of the body like the neck, armpits, or other locations where the lymph nodes are naturally located.

Skin abnormalities

Abnormal capillary formations can cause dark patches on the skin, which look similar to a hemangioma. These are usually reddish in color and can be large. They are most often seen on the lower limbs, but in 17%–21% of people with KTWS the entire limb or one side of the body is affected. The dark skin patches usually have an irregular and linear border to them. When seen on the torso of someone's body, they do not usually cross from the left to right sides. Other skin abnormalities can include smaller streaks and patches of dark skin.

Limb abnormalities

Limb enlargement is a very common sign of KTWS. In the vast majority of people, one leg is larger than the other. In others, an arm or a combination of both the arm and leg are affected. About 70% of people with KTWS have lengthening of an extremity, and an increase in thickness occurs in at least 50%.

Enlargement and vascular abnormalities usually occur together in the same limb. The enlargement of the limbs is presumed to be due to a combination of factors: underlying bone overgrowth, lymphatic swelling, muscle overgrowth, and thickened skin.

Other limb abnormalities can include enlargement of the fingers or toes, webbing between these digits, extra digits, or missing digits.

Other signs of KTWS

Glaucoma can be seen in KTWS, either first appearing at birth or in early childhood. Seizures can be

part of the condition and, rarely, intellectual disability as well.

Individuals with extensive vein or lymphatic abnormalities can develop a blood-clotting problem in which their platelet count is lower than usual. This is sometimes incorrectly referred to as the Kasabach-Merritt syndrome, which actually occurs when the blood platelet count is extremely low.

Diagnosis

As of early 2015, there was no clinical genetic testing available for KTWS. Research taking place in the United States and Belgium offers screening of genes that may be implicated in the condition, but it is only offered as part of a research study. Most people with KTWS are diagnosed because of signs and symptoms they have.

Children may first come to medical attention for KTWS at birth or shortly afterward because they are born with dark patches on their skin or a limb that is larger than the other. A careful evaluation by a team of physicians, including a pediatrician, medical geneticist, and a dermatologist, can help to identify whether the diagnosis is KTWS.

KTWS has occasionally been suspected during a pregnancy in cases where significant limb enlargement was seen on a prenatal ultrasound. One study reported a case from 1999 where a prenatal ultrasound showed that the developing baby had limb and digit enlargement with increased blood flow and fluid-filled sacs.

In this case, suspecting KTWS helped to determine the best type of delivery for the baby and the mother. The baby was born by a Caesarean section, which helped reduce the complications to him and his mother from his limb enlargement and fluid collections. When the baby was born, he was found to have large red skin patches on the affected limb, and KTWS was highly suspected.

There are symptoms of KTWS that overlap with other conditions. Sturge-Weber syndrome usually has dark skin patches and vascular abnormalities, glaucoma, seizures, and mental delays. However, significant limb enlargement is not usually a part of Sturge-Weber syndrome.

Parkes-Weber syndrome involves vascular abnormalities, but these differ from those seen in KTWS. For example, Parkes-Weber syndrome does not usually involve the lymphatic system. Additionally, Parkes-Weber syndrome can have symptoms that affect the heart, which are not typically seen in KTWS.

Treatment and management

There is no known cure for KTWS. However, treatments are available to help with some symptoms of the condition. These typically involve a large team of

specialists that may include a pediatrician, vascular surgeon, orthopedist, orthopedic surgeon, hematologist, medical geneticist, genetic counselor, ophthalmologist, neurologist, social worker, and therapist.

Custom-made compression stockings can be worn to reduce swelling, create a barrier for minor trauma, and help blood drain from an enlarged body part. Parents can find it a challenge to encourage a young child to wear such stockings, but they may work well for older children and adults. Compression stockings do not usually permanently reduce the size of the enlarged limb.

Swelling can also be reduced with manual drainage, a gentle massage of the affected area. A physical therapist, occupational therapist, or massage therapist typically performs this. Air-driven pumps can also help reduce swelling. The affected limb is covered in an air-filled plastic sleeve, which places gentle pressure to stimulate fluid movement from the swollen limb.

Some people have seen reduction in the redness of their skin patches through laser treatments using pulses of light. It may require a series of these treatments, and skin changes may still be noticeable or even unchanged after the treatment is finished.

If there is increased bleeding or a low amount of platelets is suspected, blood testing can check the platelet level. This can be carefully monitored through a series of blood tests, and in some cases a blood transfusion may be required. If a patient has internal bleeding that causes damage to some internal organs or tissues, surgery to control this bleeding or remove affected tissues may be needed.

In some cases, bacterial infections can warrant the use of antibiotics to stop the infection.

Ultrasounds, x-rays, magnetic resonance imaging (MRI) scans, lymphoscintigraphy, and angiography can help obtain details about limb enlargement. These all attempt to gain information about the specific tissues or organs affected by limb enlargement and abnormal blood flow.

Surgical treatments may be needed for some with KTWS, though the goal is often to avoid this whenever possible. Abnormal blood vessels may need to be repaired by removing them or rejoining them. Varicose veins may need to be removed, but these can sometimes return even after treatment. Women with KTWS who are pregnant may have bleeding complications depending on the location of any vascular abnormalities, and should be monitored closely during their pregnancies.

Minor leg length differences can sometimes be treated with a shoe insert that is worn on the foot of the shorter leg. If a leg causes a significant asymmetry, a procedure called epiphysiodesis may be necessary. This

KEY TERMS

Angiography—Procedure that shows the system of blood vessels and the blood flow in a portion of the body. Requires an injection of dye to help see the vessels.

Arterial—Term used to describe an artery or the entire system of arteries.

Caesarean section—Surgical method to deliver a baby that requires making an incision in the mother's abdomen to remove the infant.

Capillary—Very narrow tube that carries liquid like blood or lymphatic fluid.

Glaucoma—An eye disease that usually involves high pressure in the eye, which can lead to vision problems or blindness if left untreated.

Hemangioma—Abnormality resulting from a collection of vascular tissue like blood vessels, which can cause a dark reddish patch on the skin.

Lymphoscintigraphy—Procedure that helps to look at the lymph nodes in the body. Requires an injection of radioactive material to help see the lymph nodes and lymphatic system.

Magnetic resonance imaging (MRI) scan—Procedure that shows internal organs and tissues of the body using magnetic fields and signals.

Platelet—Cell in the blood that helps with clotting.

Ultrasound—Procedure that shows internal organs and tissues of the body using sound waves.

Venous—Term used to describe a vein or the entire system of veins.

X-ray—Procedure that shows internal organs and tissues of the body using radiation.

surgical treatment can stop bone growth in an affected leg, but requires destroying a portion of the underlying bone to do it. It must be timed well to coordinate with the normal bone growth that occurs in childhood and adolescence.

In rare cases, limb or digit amputation may be needed to improve function for a person with KTWS. This is typically done when other helpful options have not been successful.

Seizures can occur in KTWS, and these may be treated with antiseizure medications. Glaucoma may be identified from a careful eye examination and treated with eye drops, pills, ointments, or laser therapy to reduce the pressure in the eye and maintain vision.

Mental retardation is rare in KTWS, but may be assessed by a child development team or early childhood program. Extra assistance is sometimes available through early intervention programs and special education in schools. Social workers are useful to connect families to helpful resources.

A psychologist, genetic counselor, or therapist can be helpful for some with KTWS. Living with visible skin changes can be difficult, and some may find it easier to talk to an objective person or to talk with other affected families in a support group.

Prognosis

Prognosis can vary widely in KTWS. Complications, especially the vascular abnormalities, can be serious and cause death if symptoms are severe enough and treatment is not successful. The exact expected lifespan for the average person with KTWS is unknown, but is highly dependent on the symptoms experienced.

The best way to improve one's prognosis is to utilize a team of specialists that are familiar with KTWS. Through early identification and monitoring of symptoms, treatments can be started sooner and appropriate medical decisions can be made to help the individual and the family.

Kniest dysplasia

Definition

Kniest dysplasia is a form of dwarfism caused by a mutation in gene *COL2A1*, which plays a role in the normal formation of collagen tissue needed for growth.

Description

Kniest dysplasia is a rare form of congenital dwarfism. It is caused by mutations in the gene responsible for the formation of the eye's vitreous body (the gel portion inside the eyeball) and cartilage. As the human skeleton is formed, it is largely made of cartilage; therefore, a lack of cartilage seriously delays the growth of bone, as well as formation of the nose, ears, and other connective tissues that support the body.

Intelligence is not usually affected by Kniest dysplasia.

Genetic profile

Kniest dysplasia is inherited through an autosomal dominant pattern, which means that a child may inherit the disorder even if only one parent has the gene for it. The disorder is caused by mutations in the *COL2A1* gene, which is involved in the formation of collagen needed to make the gel within the eye (vitreous body) and cartilage.

Demographics

Kniest dysplasia is rare, but the exact incidence of the disorder is unknown.

Risk factors

A person is at risk for inheriting Kniest dysplasia if one parent carries the gene mutation; however, most cases develop with a new mutation that is not carried by either parent. A person who has Kniest dysplasia has a 50% chance of having a child with the disorder.

Because the ligaments are not held as tightly as in an unaffected person, the neck is vulnerable to injury in activities such as sports or in the event of an automobile accident.

Signs and symptoms

Signs that a person has Kniest dysplasia may include:

- Height. Short stature, 42–58 inches in adulthood
- Limbs. Short arms and legs with bones that are broad at either end and more narrow in the middle, sometimes referred to as “dumbbell-shaped”

KEY TERMS

Myopia—Nearsightedness.

Trachea—Also called windpipe; a tube in the upper airway.

- Fingers. Long with knob-like protrusions
- Feet. Clubfoot may be present
- Joints. Unusually large, painful, and unable to move freely
- Spine. Kyphoscoliosis (rounded back that curves to one side) and flattened vertebrae
- Face. Round, flat with eyes that bulge and are wide set
- Mouth. Cleft palate may be present at birth
- Respiratory. Infants may have difficulty breathing due to a weak trachea
- Ears. Frequent ear infections
- Eyes. Severe nearsightedness and retinal detachment

Diagnosis

Examination

On examination, a baby may exhibit some of the characteristics described such as clubfoot. Most infants will show slow growth compared to other children their age.

Tests

An x-ray examination may reveal the characteristic Swiss cheese pattern of cartilage in people with Kniest dysplasia.

Procedures

Kniest dysplasia may be diagnosed in pregnancy via chorionic villus sampling (CVS) or amniocentesis. The disorder may also appear in a sonogram performed toward the latter part of the second trimester of pregnancy.

Treatment and management

Traditional

People with Kniest dysplasia must be monitored medically throughout their lives because the disorder leaves them vulnerable to many medical conditions. In some cases, curvature of the spine is corrected through spinal fusion surgery. Eye exams are an important part of routine care, and the ophthalmologist will check these individuals for detached retina, cataracts (which may develop at an early age), or worsening myopia. Hearing

QUESTIONS TO ASK YOUR DOCTOR

- What are the major medical concerns my child will face?
- What supportive measures can be undertaken to enhance the quality of life for my child?

should be monitored. Some people with Kniest dysplasia require ear tube insertion to deal with the frequent ear infections.

Surgery poses a special risk to individuals with Kniest dysplasia because their loose ligaments make them more susceptible to neck injury. Additionally, their reduced lung capacity and airway stability add further risk. It is important for a thorough anesthesia evaluation to be performed prior to any procedure requiring anesthesia.

An orthopedist will provide routine care to people with Kniest dysplasia because of complications in the joints, such as the hips and knees, related to impaired collagen development. Hip replacements are sometimes performed to treat extensive arthritis. Kniest dysplasia cannot be prevented; however, maintaining a schedule of medical monitoring may catch some of its complications, such as retinal detachment, at an earlier stage. People with Kniest dysplasia will most likely require regular visits to primary care providers and to an ophthalmologist, orthopedist, and rheumatologist.

Home remedies

Because of the looseness of the ligaments and poorly developed cartilage, individuals with Kniest dysplasia must approach any athletic or physical activity with extreme caution.

Prognosis

Kniest dysplasia affects a variety of body systems, and the effects often worsen as the individual ages. Joints may become more swollen over time. The spine may become more curved. Problems with hearing and vision may also worsen; retinal detachment may lead to blindness.

Krabbe disease

Definition

Krabbe disease, also called globoid cell leukodystrophy, is an inherited enzyme deficiency that leads to the loss of myelin, the substance that wraps nerve cells and speeds cell communication. Most affected individuals start to show symptoms before six months of age and have progressive loss of mental and motor function. Death occurs at an average age of 13 months. Other less-common forms exist with onset in later childhood or adulthood.

Description

Myelin insulates and protects the nerves in the central and peripheral nervous system. It is essential for efficient nerve cell communication (signals) and body functions such as walking, talking, coordination, and thinking. As nerves grow, myelin is constantly being built, broken down, recycled, and rebuilt. Enzymes break down, or metabolize, fats, carbohydrates, and proteins in the body including the components of myelin.

Individuals with Krabbe disease are lacking the enzyme galactosylceramidase (GALC), which metabolizes a myelin fat component called galactosylceramide and its by-product, psychosine. Without GALC, these substances are not metabolized and accumulate in large globoid cells. For this reason, Krabbe disease is also called globoid cell leukodystrophy. Accumulation of galactosylceramide and psychosine is toxic and leads to the loss of myelin-producing cells and myelin itself. This results in impaired nerve function and the gradual loss of developmental skills such as walking and talking.

Risk factors

People at risk for Krabbe disease are those who have a family history of the condition.

Genetic profile

Krabbe disease is an autosomal recessive disorder. Affected individuals have two nonfunctional copies of the *GALC* gene. Parents of an affected child are healthy carriers and therefore have one normal *GALC* gene and one nonfunctional *GALC* gene. When both parents are carriers, each child has a 25% chance to inherit Krabbe disease, a 50% chance to be a carrier, and a 25% chance to have two normal *GALC* genes. The risk is the same for males and females. Brothers and sisters of an affected child with Krabbe disease have a 66% chance of being a carrier.

The *GALC* gene is located on chromosome 14. Over 70 mutations (gene alterations) known to cause Krabbe disease have been identified. One specific *GALC* gene deletion accounts for 45% of disease-causing mutations in those with European ancestry and 35% of disease-causing mutations in those with Mexican ancestry.

Demographics

Approximately 1 in every 100,000 infants born in the United States and Europe will develop Krabbe disease. A person with no family history of the condition has a 1 in 150 chance of being a carrier. Krabbe disease occurs in all countries and ethnic groups, but no cases have been reported in the Ashkenazi Jewish population. A Druze community in Northern Israel and two Moslem Arab villages near Jerusalem have an unusually high incidence of Krabbe disease. In these areas, about one person in every six is a carrier.

Signs and symptoms

Ninety percent of individuals with Krabbe disease have the infantile type. These infants usually have normal development in the first few months of life. Before six months of age, they become irritable, stiff, and rigid.

They may have trouble eating and may have seizures. Development regresses leading to loss of mental and muscle function. They also lose the ability to see and hear. In the end stages, these children usually cannot move, talk, or eat without a feeding tube.

Ten percent of individuals with Krabbe disease have juvenile or adult type. Children with juvenile type begin having symptoms between three and ten years of age. They gradually lose the ability to walk and think. They may also have paralysis and vision loss. Their symptoms usually progress slower than in the infantile type. Adult Krabbe disease has onset at any time after age ten. Symptoms are more general including weakness, difficulty walking, vision loss, and diminished mental abilities.

Diagnosis

There are many tests that can be performed on an individual with symptoms of Krabbe disease. The most specific test is done by measuring the level of GALC enzyme activity in blood cells or skin cells. A person with Krabbe disease has GALC activity levels that are 0% to 5% of the normal amount. Individuals with later onset Krabbe disease may have more variable GALC activity levels. This testing is done in specialized laboratories that have experience with this disease.

The fluid of the brain and spinal cord (cerebrospinal fluid) can also be tested to measure the amount of protein. This fluid usually contains very little protein, but the protein level is elevated in infantile Krabbe disease. Nerve-conduction velocity tests can be performed to measure the speed at which the nerve cells transmit their signals. Individuals with Krabbe disease will have slowed nerve conduction. Brain imaging studies such as computerized tomography (CT scan) and magnetic resonance imaging (MRI) are used to get pictures from inside the brain. These pictures will show loss of myelin in individuals with Krabbe disease.

DNA testing for *GALC* mutations is not generally used to make a diagnosis in someone with symptoms, but it can be performed after diagnosis. If an affected person has identifiable known mutations, other family members can be offered DNA testing to find out if they are carriers. This is helpful since the GALC enzyme test is not always accurate in identifying healthy carriers of Krabbe disease.

If an unborn baby is at risk to inherit Krabbe disease, prenatal diagnosis is available. Fetal tissue can be obtained through chorionic villus sampling (CVS) or amniocentesis. Cells obtained from either procedure can be used to measure GALC enzyme activity levels. If both parents have identified known *GALC* gene mutations, DNA testing can also be performed on the fetal cells to

QUESTIONS TO ASK YOUR DOCTOR

- What kind of nervous system damage has Krabbe disease caused?
- What are the treatment options?
- Is stem cell transplant possible?
- What are the likely outcomes?

determine if the fetus inherited one, two, or no *GALC* gene mutations.

Some centers offer preimplantation diagnosis if both parents have known *GALC* gene mutations. In vitro fertilization (IVF) is used to create embryos in the laboratory. DNA testing is performed on one or two cells taken from the early embryo. Only embryos that did not inherit Krabbe disease are implanted into the mother's womb. This is an option for parents who want a biological child but do not wish to face the possibility of terminating an affected pregnancy.

Treatment and management

The treatment team for a child with Krabbe disease should include a neurologist, general surgeon to place certain types of feeding tubes, and a hematologist if bone marrow or stem cell transplants are being considered. Physical and occupational therapists can help plan for daily care of the child and provide exercises to decrease muscle rigidity. Genetic testing is recommended for persons with a family history of Krabbe disease who are planning to have children.

Traditional

Once a child with infantile Krabbe disease starts to show symptoms, there is little effective treatment. Supportive care can be given to keep the child as comfortable as possible and to counteract the rigid muscle tone. Medications can be given to control seizures. When a child can no longer eat normally, feeding tubes can be placed to provide nourishment.

Alternative

Affected children who are diagnosed before developing symptoms (such as through prenatal diagnosis) can undergo bone marrow transplant or stem cell transplant. The goal of these procedures is to destroy the bone marrow which produces the blood and immune system cells. After the destruction of the bone marrow, cells from a healthy donor are injected. If successful, the healthy cells travel to the bone

marrow and reproduce. Some children have received these transplants and had a slowing of their symptoms' progression or even improvement of their symptoms. However, these procedures are not always successful, and research is being done in order to reduce complications.

Scientists are also researching gene therapy for Krabbe disease. This involves introducing a normal *GALC* gene into the cells of the affected child. The goal is for the cells to integrate the new *GALC* gene into its DNA and copy it, producing functional *GALC* enzyme. This is still in research stages and is not being performed clinically.

Prognosis

Prognosis for infantile and juvenile Krabbe disease is very poor. Individuals with infantile type usually die at an average age of 13 months. Death usually occurs within a year after the child shows symptoms and is diagnosed. Children with juvenile type may survive longer after diagnosis but death usually occurs within a few years. Adult Krabbe disease is more variable and difficult to predict, but death usually occurs two to seven years after diagnosis.

L1 syndrome

Definition

L1 syndrome, formerly known as X-linked hydrocephaly, is a genetic disorder resulting in hydrocephaly. Hydrocephaly is the accumulation of cerebrospinal fluid (CSF) in fluid-filled cavities, called ventricles, that are located deep in the core of the brain. This disorder results from an X-linked mutation causing an alteration in the L1 cell adhesion molecule (L1CAM).

Description

Cell adhesion molecules (CAMs) provide the traffic signals that guide the cells of developing organs to migrate to their proper places and make the appropriate connections with the cells with which they interact. The L1CAM protein is embedded in the membrane of nerve cell axons, which are projections from the nerve cell body that carry impulses to sometimes distant targets. As a developing axon grows toward its target, its leading end is capped by a growth cone similar in function to that of a plant root. The growth cone of a developing axon is rich in L1CAM. The L1CAM protein has a large, complex extracellular domain (portion of the protein outside the nerve cell), a transmembrane domain within the nerve cell membrane, and a small intracellular domain (portion inside the nerve cell). The extracellular domain acts as a feeler and binds to CAMs that are either on the surface of other cells or floating in the extracellular fluid. The binding of the L1CAM protein to various CAMs in its environment sends signals into the nerve cell that direct the projecting axon to grow to the appropriate length, follow the course required for it to reach its target, and stop when appropriate.

The L1CAM protein is critical for proper development of several long fiber tracts in the forebrain. These include the corpus callosum, which is a thick fiber bridge that connects the left and right cerebral hemispheres, and the cerebrospinal tract, which extends from the motor control region of the cerebral cortex down to the spinal cord.

The developing axon often extends many cell diameters away from the cell body and must interact with CAMs from many different sources to ensure that it follows the correct route to its target. The complex extracellular domain of the L1CAM protein interacts with a variety of CAMs in the environment to serve several important functions. Because of the many functions L1CAM serves, the specific brain changes and functional handicaps that are seen in any individual patient with an L1CAM mutation depend on which of L1CAM's functions are lost and which are spared by the specific mutation that occurs in the *L1CAM* gene. Most families have their own unique L1CAM mutation. Some mutations abolish all of L1CAM's functions, while others change only a small piece of the L1CAM protein. Therefore, there is marked variability between patients in terms of which brain structures are most affected and what the primary physical and behavioral symptoms will be. Because of this variability, patients with different L1CAM mutations have been given diagnoses such as X-linked hydrocephaly (XLH), X-linked spastic paraplegia type 1 (SPG1), hydrocephaly with stenosis of the aqueduct of Sylvius (HSAS), X-linked agenesis of the corpus callosum (XLACC), and MASA syndrome (mental impairment, aphasia, shuffling gait, adducted thumbs). Because these patients all presented with such different combinations of brain changes and functional handicaps, it was originally thought that these were all distinct disorders with different biological causes. An effort has been made to unite these disorders under the general heading "L1CAM spectrum" to reflect the fact that these are not distinct disorders, but merely alternative possible consequences of L1CAM mutations.

Genetic profile

The *L1CAM* gene is located close to the end of the long arm of the X chromosome, in the band referred to as Xq28. Since the *L1CAM* gene is on the X chromosome, usually only males are affected. This is because females have two X chromosomes, while males only have one. In

X-linked hydrocephaly: pedigree analysis chart (Gale)

a female, if one X chromosome has an *L1CAM* mutation on it, the nonmutated *L1CAM* gene on the other X chromosome can usually provide enough good L1CAM protein to support normal brain development. Males, on the other hand, having only one X chromosome, cannot compensate for an X-linked gene mutation.

The inheritance pattern for L1CAM spectrum disorders follows the typical X-linked inheritance pattern. Males are usually the only ones affected, and most females who carry L1CAM mutations are unaffected. There may be several affected brothers in a single family. In addition, in a family in which the L1CAM mutation has been passed through several generations, the normally developed mothers of affected males may have affected brothers, or the normally developed sisters of affected males may have affected sons. If a female carries a mutation in L1CAM, she has a 50% chance of passing the mutation to each of her children. Therefore, approximately half her sons will be affected, and approximately half her daughters will be carriers. There is no known case in which an affected male has reproduced.

L1CAM mutations exhibit 100% penetrance, meaning that any male who has the L1CAM mutation will be affected, albeit with varying degrees of severity. This contrasts with some other disorders, in which some family members are unaffected despite having the same gene mutation that has been seen in other affected family members.

Demographics

The incidence of hydrocephaly from all causes is approximately 1 in 2,000 live births in the general population. The X-linked form is thought to account for approximately 5% of the total cases of hydrocephaly, or approximately 1 in 30,000 males. In very rare cases a

female may be affected, usually mildly. There are no systematic data comparing the incidence of L1CAM spectrum disorders in different races.

Signs and symptoms

Most patients with mutations in L1CAM exhibit intellectual disability, the degree of which can vary from mild to severe. The vast majority also exhibit hydrocephaly, which can be mild and not require any medical intervention, or severe enough to be life-threatening. The most severe cases of hydrocephaly are associated with stenosis (narrowing or pinching closed) of the aqueduct of Sylvius. The aqueduct of Sylvius (also called the cerebral aqueduct) is a narrow channel connecting the third ventricle, located deep in the midbrain, to the fourth ventricle, located underneath the cerebellum in the posterior part of the brain. The brain's cerebrospinal fluid (CSF) is made by cells lining the first two ventricles, called the lateral ventricles, which are located in the forebrain. The CSF normally flows from the first two ventricles, through the third ventricle, then into the fourth ventricle, before flowing out of the brain. Stenosis of the aqueduct of Sylvius stops the outflow of CSF and causes an accumulation of fluid and pressure, primarily in the first two ventricles. Since there is no mechanism to stop CSF production in the lateral ventricles, this form of hydrocephaly is progressive. The pressure can become so great that it stretches the developing skull bones, which are still not fully hardened, resulting in the child having a head that is visibly enlarged (macrocephaly). In the process, the brain tissue is pressed against the skull, with predictably devastating effects on brain function. Many of the more severely hydrocephalic patients are either stillborn or die within one year of birth.

KEY TERMS

Adducted thumbs—Thumbs clasped across the palm.

Aphasia—Impairment of the ability to comprehend or communicate through speech, writing, or signs due to brain dysfunctions.

Brain ventricles—A set of four connected cavities that are located deep in the core of the brain. Cerebrospinal fluid (CSF) is made by cells lining the walls of the first two ventricles, then flows through the third, then through the fourth ventricle, before flowing out of the brain. The fluid-filled cavities provide mechanical cushion for the brain, and the CSF provides nutrients to, and carries metabolic wastes away from, the cells of the brain.

Cell adhesion molecule—Any one of several thousand proteins that together control the cell-to-cell communication that must take place in order for cells to migrate to their proper places, develop into the proper types of cells, and make the appropriate connections with other cells.

Corpus callosum—A thick bundle of nerve fibers deep in the center of the forebrain that provides

communications between the right and left cerebral hemispheres.

Corticospinal tract—A bundle of long nerve fibers that runs from the motor control region of the cerebral cortex to the spinal cord, where it connects to nerves that control movement in the legs.

Hydrocephaly—An increase of cerebrospinal fluid in the brain.

Macrocephaly—An unusually large head.

Penetrance—The frequency with which a heritable trait is manifested by individuals carrying the principal gene or genes conditioning it, usually expressed as a percentage.

Spastic paraplegia—Inability to walk, due to lack of proper neural control over the leg muscles.

Stenosis—The constricting or narrowing of an opening or passageway.

Ventriculoperitoneal shunt—A tube equipped with a low pressure valve, one end of which is inserted into the lateral ventricles, the other end of which is routed into the peritoneum, or abdominal cavity.

X-linked—A genetic trait that is carried on the X chromosome.

Approximately 80% of patients with *L1CAM* mutations exhibit adducted thumbs (clasped across the palm). A smaller percentage exhibit aphasia (lack of speech) or problems with leg control that range from walking with a shuffling gait to spastic paraplegia that leaves them unable to walk at all.

The most common finding in brain imaging studies is the absence (agenesis) or underdevelopment (hypoplasia) of the corpus callosum. The corpus callosum is a large fiber tract that projects between the left and right hemispheres of the brain and enables information to be transferred from one hemisphere to the other. It is uncertain whether the abnormalities in the corpus callosum are an important cause of these patients' intellectual disability. It is most likely that the pressure exerted on the developing brain tissue by the hydrocephaly is a more consistent and important cause of the intellectual disability seen in these patients. Another brain structure seen to be underdeveloped in some patients with *L1CAM* mutations is the corticospinal tract. The corticospinal tract begins in the motor control region of the cerebral cortex and runs downward to connect with the spinal cord neurons that control the legs. Abnormal development of the corticospinal tract is

probably the cause of the shuffling gait/spastic paraplegia seen in some patients with *L1CAM* mutations.

Diagnosis

In the more severely hydrocephalic patients, hydrocephaly can be seen by ultrasound at 20 weeks gestation, or approximately halfway through the fetal period. For less severely affected patients, some degree of hydrocephaly is usually noted within a year after birth, along with a general developmental delay. These babies do not roll over, sit up, or reach for objects as early as babies typically do. In rarer cases, some mildly affected patients are not diagnosed until an age at which speech problems or problems with their walking gait can be observed. Adducted thumbs, when present, are noticeable from birth or sometimes upon ultrasound analysis.

Genetic testing involves a search for mutations in the *L1CAM* gene in patients with *L1CAM* spectrum disorders. The sequence of the *L1CAM* gene from the affected patient is compared to the normal *L1CAM* sequence. DNA is usually obtained from a blood sample for postnatal diagnosis. For prenatal diagnosis, DNA can be

QUESTIONS TO ASK YOUR DOCTOR

- How beneficial will modes of treatment such as physical, occupational, or speech therapy be for my child?
- What are the risks and benefits of shunting?
- What is the level of severity of my child's case of L1 syndrome?
- Which family members should undergo genetic testing?

extracted from amniotic fluid cells obtained by amniocentesis, or from chorionic villus sampling (CVS).

Treatment and management

In the most severely hydrocephalic cases, the baby must be delivered by cesarian section because the head has grown too large by the end of the pregnancy for the baby to be delivered vaginally. For the more severely affected patients, a ventriculoperitoneal shunt can be used to reduce the pressure inside the brain. The shunt is a tube inserted into the lateral ventricles that allows the CSF to drain into the peritoneum, or abdominal cavity. This provides a means for the CSF to flow out of the brain in cases of HSAS in which the aqueduct of Sylvius has been closed and the CSF cannot flow out of the brain by the usual channel. Shunting markedly reduces the pressure on the brain and has saved many patients' lives. However, shunting will not prevent these patients from having intellectual disability or other L1CAM spectrum features.

Other methods for managing cases of L1CAM spectrum disorders are focused on the specific features the individual patient exhibits. Special education is almost always necessary, with the specific program designed to accommodate the degree of cognitive disability seen in the individual patient. Physical therapy and mechanical aids such as walkers can be used to help patients with milder degrees of spastic paraplegia. Speech therapy has also benefited some of the less severely aphasic patients. There is generally little improvement when these therapies are applied to more severely affected patients.

Prognosis

The prognosis for patients with L1CAM mutations is highly variable. The most severe cases of L1CAM mutations involve fetal demise, presumably because of the pressure exerted on the developing brain by the hydrocephaly. However, in less severe cases, the lifespan is

determined primarily by general health and care factors. A number of patients with less severe L1CAM spectrum disorders have lived at least into their 50s.

Langer-Saldino achondrogenesis

Definition

Langer-Saldino achondrogenesis is a rare genetic disorder that affects the development of bones and

connective tissues (fibrous tissues, such as tendons and cartilage that support body tissues and organs). Although it is a genetic disorder, it is not inherited. This condition is often fatal in infancy. Typical symptoms include a small body with short limbs and poor lung development.

Description

Achondrogenesis is a collection of disorders that affect the development of bone and connective tissues. There are at least three types of achondrogenesis:

- Houston-Harris achondrogenesis, also known as type 1A
- Parenti-Fraccaro achondrogenesis, also known as type 1B
- Langer-Saldino achondrogenesis, also known as type II (or type 2)

Symptoms of the three types are somewhat similar, and all three result from genetic mutations.

Mutations in the *COL2A1* (collagen, type II, alpha 1) gene are associated with Langer-Saldino achondrogenesis. Mutations in this gene affect the body's ability to make a type of collagen. Collagen is a fibrous protein that is the main constituent of bones and connective tissues. Specifically, this gene produces type II collagen, which is the primary protein in cartilage. Type II collagen is necessary for the development of bones and connective tissues. In Langer-Saldino achondrogenesis, type II collagen protein is not formed, bones and connective tissues do not develop as they should, and the affected individual has a range of skeletal and other problems.

Langer-Saldino achondrogenesis is fatal. The presence of a mutated *COL2A1* gene may result in stillbirth. Infants who are born with the disorder often have hydrops fetalis, a condition in which massive fluid accumulation causes the limbs to swell and makes breathing difficult. Babies with hydrops fetalis often die. Those rare children who survive infancy typically live no longer than their early teens.

Symptoms of Langer-Saldino achondrogenesis

Short trunk
Extremely short limbs
Short neck supporting a comparatively large head
Distinctive facial features, including a small chin and large forehead
Narrow chest with short ribs
Underdeveloped lungs
Hydrops fetalis
Incomplete bone development in the backbone and in the hips
Cleft palate in some cases
Large abdomen

(Gale)

KEY TERMS

Amino acids—Building blocks of proteins.

Collagen—Fibrous protein that is the main constituent of bones and connective tissues.

Connective tissues—Fibrous tissues, such as tendons and cartilage that support body tissues and organs.

Hydrops fetalis—A condition in which massive fluid accumulation causes the limbs to swell and breathing to be difficult.

Hypochondrogenesis—A condition similar to Langer-Saldino achondrogenesis caused by different mutations in the *COL2A1* gene.

Micromelia—Extremely short arms and legs.

Procollagen—A collagen precursor formed by the twisting together of three pro-alpha1(II) chains.

Vitreous humor of the eye—The clear gel inside the eyeball.

Genetic profile

Langer-Saldino achondrogenesis is caused by spontaneous mutations in the *COL2A1* gene. This means that an affected child did not inherit the mutation; rather, the mutation developed in the egg or sperm cell, or during early embryonic development. Individuals with this disorder do not live into their reproductive years, so the disorder is not passed down from one generation to the next.

The *COL2A1* gene, located on the long arm (q) of chromosome 12 at 12q13.11, carries the blueprint for making certain components of type II collagen. These components are called pro-alpha1(II) chains, and three of them twist together into a coil-like structure known as procollagen. The procollagen molecules then go through another step involving an enzyme to become long strands that form a meshwork in the spaces around cells. These long strands are known as mature type II collagen fibers. The strong meshwork of the type II collagen fibers provides the framework to support large body structures, including muscles, organs, and skin, and is important in skeletal development. Type II collagen is also found in the vitreous humor of the eye (the clear gel inside the eyeball).

Scientists know of at least 18 different mutations in the *COL2A1* gene that can lead to Langer-Saldino achondrogenesis. These mutations all result in the substitution of a single glycine amino acid (a building block of protein) with another amino acid at one of several different positions in the collagen protein chain. These substitutions all prevent the production of mature type II collagen

fibers. Different mutations in the *COL2A1* gene can result in various other genetic disorders.

Demographics

Langer-Saldino achondrogenesis is a rare genetic disorder that affects individuals of various ethnicities and geographic areas with the same frequency. It is similar to hypochondrogenesis, which is caused by mutations in the same gene and has similar symptoms; thus, the National Institutes of Health report the incidence of the two diseases as a combined number. Langer-Saldino achondrogenesis and hypochondrogenesis together affect 1 in 40,000–60,000 newborns.

Signs and symptoms

Typical symptoms of Langer-Saldino achondrogenesis include:

- a short trunk
- extremely short limbs (micromelia)
- a short neck supporting a comparatively large head
- distinctive facial features, including a small chin and large forehead
- a narrow chest with short ribs
- underdeveloped lungs
- hydrops fetalis
- incomplete bone development in the backbone and in the hips
- a large abdomen
- a cleft palate in some cases

In addition, babies with achondrogenesis are born in the breech position (feet first) more often than healthy babies.

Diagnosis

Since Langer-Saldino achondrogenesis results from a spontaneous rather than an inherited mutation, the patient's family history is not helpful in its diagnosis. Often, the first signs of a potential problem arise during traditional prenatal care, when a technician notices fetal anomalies during an ultrasound examination. These anomalies may include severe micromelia, a narrow chest, and a lack of bone development in the spine and pelvis.

Examination

The doctor will review the ultrasound to confirm the anomalies. If achondrogenesis is not identified before birth, x-rays at birth verify the extent of skeletal abnormalities, although a visual examination of the infant

QUESTIONS TO ASK YOUR DOCTOR

- What treatments are available to make my child as comfortable as possible?
- I have a child with Langer-Saldino achondrogenesis. What are the chances that I will have a second child in the future with this disorder?
- We lost a child to Langer-Saldino achondrogenesis. What alternatives are available to ensure that our next child does not have this disorder?
- What would be the benefit of having DNA testing to determine which type of achondrogenesis my child has?
- Is prenatal testing available for Langer-Saldino achondrogenesis?

may be sufficient. A DNA analysis may be ordered to confirm the specific type of achondrogenesis.

Treatment and management

No cure is available for Langer-Saldino achondrogenesis. Doctors are sometimes, but not always, able to assist with a patient's breathing problems. Physical therapy may be helpful in assisting with overall body movement. Treatments for many symptoms, however, are not available.

Prognosis

Prenatal death is common. Infants who are born with this disorder often die shortly after birth, typically due to underdeveloped lungs. Rarely, individuals survive into childhood, and rarer still, into their early teens. There is no way to prevent Langer-Saldino achondrogenesis. It is a disorder that results from a spontaneous genetic mutation. If this condition is diagnosed during pregnancy, parents should consult their doctor for advice and referrals so they can prepare for the birth or otherwise determine how they wish to respond to the diagnosis.

Larsen syndrome

Definition

Larsen syndrome (LRS) is an inherited condition characterized by congenital dislocation of multiple body joints along with other unusual features of the face, hands, and bones.

Description

This condition was first described in 1950 by Larsen, Schottstaedt, and Bost, who compiled information on six people with sporadic cases of LRS. It is named for Loren Larsen, the orthopedic surgeon who was the first author of the original study.

LRS has been called both a skeletal dysplasia (a condition caused by abnormalities of bone structure) and a hypermobility syndrome (a condition involving abnormally loose joints). It is most likely caused by inherited abnormalities of connective tissue that affect both bone and joint structure. It is sometimes classified as an *FLNB*-related disorder because it is now known to be caused by mutations in the *FLNB* gene. Other disorders in the *FLNB*-related group include atelosteogenesis, types 1 and 3, boomerang dysplasia, and spondylocarpotarsal syndrome (SCT).

Present at birth are multiple dislocations of the elbows, hips, and, most commonly, the knees. Persons with LRS have other distinctive physical features that

can include a prominent forehead, widely spaced eyes, long cylindrical fingers, and short bones of the hand. Sometimes present are other birth defects such as structural heart defects, cleft palate, cataracts, extra bones of the wrist, and abnormalities of the vertebrae.

Most people have moderate symptoms that can be treated, allowing for a relatively normal lifespan. However, a small number of babies have a severe form of the condition and die at birth.

Genetic profile

There are likely to be multiple causes for LRS. Both recessive and dominant patterns of inheritance have been described thus far.

Some cases are sporadic, meaning the affected person is the first in the family to have the condition. Many sporadic cases are thought to be caused by new dominant mutations (spontaneous changes in the genetic material). A person with sporadic LRS has a change in the genetic material that is not present in either parent but can be passed on, with 50/50 odds in each child, to his or her offspring.

Patients have been reported who have affected brothers or sisters but unaffected parents. Most of these cases probably represent a recessive form of LRS in which a person must have two copies of a genetic change in order to be affected. The parents of a person with a recessive condition must each have one copy of the genetic change in order to have an affected child.

There are rare instances in which a person with LRS appears to have the recessive form but then gives birth to an affected child. These cases are most likely dominant rather than recessive. It can be difficult to be certain of the inheritance pattern in some families, and genetic counselors must be careful to address both forms of inheritance when discussing chances of recurrence.

The autosomal dominant form of LRS is thought to be caused by mutations in a gene called *FLNB* on the short arm of chromosome 3 at 3p14.3. The *FLNB* gene codes for a protein called filamin B, which is important in the formation and development of cartilage in the fetus before birth. The *FLNB* mutation associated with LRS results in an abnormal protein that interferes with the normal production of cartilage and the later maturation of cartilage into bone as the child grows older.

Another dominantly inherited condition called atelosteogenesis type 3 (AOIII) has features that overlap with those of LRS, and is caused by mutations in the same gene. As of 2015, at least six different mutations of the *FLNB* gene had been identified as causing AOIII.

Demographics

LRS is an extremely rare genetic condition that occurs in about 1 in every 100,000 to 250,000 births, although some researchers suspect that it is underdiagnosed because the symptoms can be confused with those of other skeletal or joint disorders.

Signs and symptoms

The symptoms of LRS vary widely from person to person and can range from lethal to very mild, even among members of the same family.

Typical characteristics at birth are multiple joint dislocations that can include hips, elbows, wrists, and knees. Babies can be born with their knees in hyperextension with their ankles and feet up by their ears, a deformation called genu recurvatum. Clubfoot is common, and persistent flexion, or contractures, of such other joints as the wrist and fingers can also occur.

Persons with LRS often have distinctive facial features. Common findings, in addition to a large forehead and wide-spaced eyes, are flat cheekbones and a flat bridge of the nose, which is sometimes indented and called “saddle nose.” The hands are often short, but the fingers are long and lack the normal tapered ends.

Other birth defects can occur but are not present in all people. Cleft palate, cataracts, and heart defects of the valves or between the upper or lower chambers occur occasionally.

Often, babies have poor muscle tone (hypotonia), giving them a “rag doll” appearance. Respiratory problems are frequently seen at birth because of laxity of the trachea. Feeding and swallowing difficulties are common.

Abnormalities of the bones are frequent. Underdevelopment and abnormal shape of some of the vertebral bones can lead to problems such as scoliosis or kyphosis. Abnormalities of the epiphyses (centers of bone growth) can develop in childhood. Height is often reduced, and an adult height of 4–5 ft (1.2–1.5 m) is not uncommon. The joints between the bones of the ear may be abnormal and may cause conductive hearing loss.

Hypermobility of joints lasts throughout life and may lead to early-onset arthritis and recurrent dislocations, which may necessitate joint replacement at an early age. Cervical spine instability is a very serious complication of LRS, as it can cause compression of the spinal cord and lead to paralysis or death.

The condition does not affect intelligence, and children can expect to have normal school experiences, with

KEY TERMS

Arthrogryposis—Abnormal joint contracture.

Carrier—A person who possesses a gene for an abnormal trait without showing signs of the disorder. The person may pass the abnormal gene on to offspring.

Clubfoot—Abnormal permanent bending of the ankle and foot; also called talipes equinovarus.

Congenital—Refers to a disorder that is present at birth.

Connective tissue—A group of tissues responsible for support throughout the body; includes cartilage, bone, fat, tissue underlying skin, and tissues that support organs, blood vessels, and nerves throughout the body.

Contracture—A tightening of muscles that prevents normal movement of the associated limb or other body part.

Deformation—An abnormal form or position of a part of the body caused by extrinsic pressure or mechanical forces.

Epiphysis (plural, epiphyses)—The end of long bones, usually terminating in a joint.

Hypermobility—Unusual flexibility of the joints, allowing them to be bent or moved beyond their normal range of motion.

Joint dislocation—The displacement of a bone from its socket or normal position.

Kyphosis—An abnormal outward curvature of the spine, with a hump at the upper back.

Magnetic resonance imaging (MRI)—A technique that employs magnetic fields and radio waves to create detailed images of internal body structures and organs, including the brain.

Scoliosis—An abnormal side-to-side curvature of the spine.

Skeletal dysplasia—A group of syndromes consisting of abnormal prenatal bone development and growth.

the exception of physical education, which will need to be adapted to each child's needs.

Diagnosis

LRS should be suspected in any baby having multiple joint dislocations at birth. Babies suspected of

QUESTIONS TO ASK YOUR DOCTOR

- At what point in fetal or child development can Larsen syndrome be diagnosed?
- What tests or other measures are used to diagnose Larsen syndrome?
- What are the stages that normally occur in the development of Larsen syndrome in a child?
- Are there parent or research organizations that can provide me with additional information about my child's Larsen syndrome?

having the condition warrant a complete evaluation by a medical geneticist (a physician specializing in genetic syndromes).

LRS is sometimes misdiagnosed as another condition called arthrogryposis, which involves multiple joint contractures. LRS can be distinguished from this and other syndromes involving joint dislocations or contractures because of the unusual constellation of features found in the face and hands. Extra bones of the wrist, often seen in LRS, are extremely rare in other syndromes.

Some people have very mild symptoms and may not have joint dislocations or other problems at birth. The diagnosis can be missed in these people unless they are carefully evaluated.

A person with dominantly inherited LRS has a 50% chance with each pregnancy of having a child with the same disorder. Genetic counseling can help couples sort out their options for parenthood. Some couples choose to adopt rather than take the chance of an affected child, others go ahead with a pregnancy, and others choose to have prenatal diagnosis. The usual form of prenatal diagnosis available to date is ultrasound.

Fetal ultrasound performed by a specialist at 18–20 weeks of pregnancy can sometimes reveal signs of LRS. Some symptoms that can be noted during fetal ultrasound include knee dislocations and hyperextension; club feet; fixed flexion of elbows, wrists, and fingers; and some of the characteristic facial features. Physical findings from ultrasound can suggest, but do not confirm, the diagnosis of LRS in a fetus. As of 2015, the diagnosis could be confirmed before birth by molecular genetic testing, either sequence analysis of the entire coding region or deletion/duplication analysis. There is a test for the *FLNB* gene by itself, as well as genetic panel tests that check for 30 or more genes associated with skeletal and joint abnormalities.

Treatment and management

Treatment varies according to the symptoms of a particular child. Joint problems require long-term orthopedic care. Dislocations, clubfeet, and joint contractures are treated with intensive physical therapy, splints, casting, and/or surgery. Physical therapy is also important after joint surgery to build up muscles around the joint and preserve joint stability. Occupational therapy may be helpful for children with wrist and finger contractures.

Respiratory problems at birth may necessitate oxygen or assistive breathing devices. If not alleviated by medication or special feeding techniques, eating and swallowing problems may require tube feeding. Heart problems, cleft palate, and cataracts often warrant surgical correction. Special care is needed if laxity of the trachea is present because of an increased risk for respiratory problems during and after surgery.

People with chronic pain associated with hypermobile joints often can be helped by techniques taught in a pain management clinic.

Magnetic resonance imaging of the neck is recommended in childhood to screen for cervical vertebral problems. Early diagnosis and surgical stabilization of the spine can help patients avoid paralysis and death from spinal cord compression. Scoliosis is usually treated by bracing or by a surgically placed metal rod. Artificial hip and knee replacements may be needed in early-to-mid adulthood because of degeneration of unstable joints.

Regular medical examinations are crucial to assess the condition of the bones, joints, spine, heart, and eyes. Hearing should be evaluated on a periodic basis, especially in children, because of the potential for conductive hearing loss. Ophthalmologic examinations are recommended periodically to screen for cataracts.

Prognosis

The effects of the syndrome vary markedly from person to person. Therefore, prognosis is based on the findings in a given individual. The usual causes of early death are either severe respiratory problems or compression of the cervical spine from vertebral instability.

If careful and consistent orthopedic treatment is initiated early, prognosis can be good, with a normal lifespan. Weak and unstable joints and limited range of motion from contractures may cause walking difficulties and restrict other physical activities. Knee or hip replacement may be needed in early adult life. Contact sports and heavy lifting should be avoided, as anything that puts extra strain or pressure on the joints can cause harm. Swimming is a good activity because it helps strengthen muscles without joint strain.

Laterality sequence

Definition

Laterality sequence refers to a variable group of developmental anomalies in which some or all of an affected individual's internal organs form on the opposite side of the body than is standard. The heart, stomach, and spleen may form on the right side of the body instead of the left. The liver and gallbladder may form on the left side of the body instead of the right. Laterality refers to a side of the body. A sequence is a chain of events that occurs as a result of a single abnormality or problem.

Description

All humans display a characteristic placement of internal organs, with the heart, stomach, and spleen toward the left and the liver and gallbladder on the right. This placement of organs is called situs solitus. Very early in fetal development, the embryo forms a left-right axis that determines which side is left and which side is right. The axis can then instruct the body to form organs toward one side or the other. When the left-right axis does not form correctly, all or some of the organs form in the wrong location and result in a laterality sequence defect.

The first documented cases of laterality sequence occurred in the 1600s with Fabricius's description of an individual's symptoms of reversed liver and spleen and Marco Severino's recognition of dextrocardia. Laterality sequence defects range in features and descriptions. Features of laterality sequence anomalies include abnormal placement of all or some organs, dextrocardia (heart on the right side of the body), asplenia (no spleen), polysplenia (multiple spleens), complex congenital heart defects, intestinal malrotation, abnormal lung formation, symmetrical liver, midline abnormalities, and neural tube defects. Other terms for laterality sequence defects include situs inversus, situs inversus viscerum, situs transverses, heterotaxy, situs ambiguous, isomerism sequence, asplenia syndrome, Ivemark syndrome, polysplenia syndrome, partial situs inversus, and dextrocardia.

Genetic profile

Laterality sequence defects can occur due to genetic or multifactorial causes. Most cases of laterality sequence defects are sporadic and multifactorial. Multifactorial conditions result from the combination of environmental and genetic factors that contribute to the development of laterality sequence defects. First-degree relatives of an individual affected by a multifactorial condition have an increased risk that is based on family studies. A family that has one child with an isolated case of a laterality sequence, with no other affected children, runs a 3%–5% risk of having a future child affected by a laterality sequence defect.

Although all of the genes that are known to be involved in laterality sequence defects encode proteins that help determine the laterality of an individual, the inheritance pattern of inherited laterality sequence defects depends on the specific gene defect. New genetic mutations that cause laterality defects are still being discovered. Genes currently associated with laterality defects include *ZIC3* (also known as *HTX1*, zinc finger protein *ZIC3*, Xq26.2), *CRELD1* (Cysteine-rich with EGF-like domains located at 3p25.3), *DNAH11*, *LEFTB* (formerly *LEFTY2*), *CRC* (CRYPTIC located on chromosome 2),

EBAF (transforming growth factor beta 1q42.1), *NKX2* (homeobox protein Nkx-2.55 5q34), and *ACVR2B* (encoding activin receptor IIB located at 3p22-p21.3).

Most cases of inherited laterality defects travel through the family in an autosomal recessive manner. In an autosomal recessive condition, two copies of the mutant, or nonworking, gene are needed for a person to develop the symptoms of laterality sequence. In these cases, each parent carries one copy of a mutant gene. Individuals with only one copy of a nonworking gene for a recessive condition are known as carriers and have no problems related to the condition. However, when two people with the same mutant recessive gene have children together, there is a 25% chance with each pregnancy for the child to inherit two mutant copies, one from each parent. That child then has no working copies of the gene and, therefore, has the signs and symptoms associated with genetic defects. Gene mutations that result in autosomal recessive forms of laterality defects include *DNAH11*. *DNAH11*, located on the short arm of chromosome 7 (7p21), is expressed in the node of the embryo at day 7.5 and is involved in left-right axis determination of the organs. Mutations in the coding region of *DNAH11* account for situs inversus totalis.

Additional autosomal recessive laterality defects can also be a feature of other inherited conditions, such as Kartagener syndrome and Ivemark syndrome. Kartagener syndrome is an autosomal recessive disorder characterized by bronchiectasis, sinusitis, dextrocardia, and infertility that can be caused by several different genetic locations and mutations. Approximately 25% of individuals affected by situs inversus have Kartagener syndrome. Ivemark syndrome refers to the congenital absence of the spleen, usually accompanied by complex cardiac malformations, malposition and maldevelopment of the abdominal organs, and abnormal lobation of the lungs.

Some cases of laterality sequence defects are inherited in an autosomal dominant pattern. In an autosomal dominant inheritance pattern, the genes that cause laterality sequence are carried on one of the 22 pairs of numbered autosomal chromosomes, rather than on the X or Y sex chromosomes. Furthermore, in autosomal dominant conditions, only one copy of the mutant, or nonworking, gene is necessary for the development of laterality sequence. An individual who inherits a normal gene copy from one parent and an abnormal gene copy from the other parent is likely to have a lateral sequence anomaly. The children of an individual with one normal gene copy and one mutated copy have a 50% chance of inheriting laterality sequence. One known form of laterality sequence that is found inherited in an autosomal dominant manner occurs in patients with a nonworking copy

of *CFC1*. *CFC1* is located on chromosome 2 and is involved in the formation of the left-to-right axis in human development. Accordingly, individuals who have one nonworking copy of *CFC1* have randomized organ positioning (heterotaxia). In addition to the forms of laterality sequence described earlier, as of 2015 there had been eight other genes described that were known to be associated with the autosomal recessive form of this condition.

Some cases of laterality sequence defects are inherited in an X-linked recessive pattern. As opposed to genes that are carried on one of the 22 pairs of numbered autosomal chromosomes, X-linked genes are found on the sex chromosomes called X. Females have two X chromosomes, while males have a single X chromosome and a single Y chromosome. When a female inherits a mutated gene on the X chromosome, she is known as a carrier. She often has no problems related to that condition because the gene on her other chromosome continues to function properly. However, males only inherit one copy of the information stored on the X chromosome. When a male inherits a mutated copy of the gene that causes an X-linked recessive condition, he will experience the symptoms associated with the disease. The chance for a carrier female to have an affected son is 50%, while the chance to have an unaffected son is 50%. The chance for a carrier female to have a daughter who is also a carrier for the condition is 50%, while the chance for her to have a daughter who is not a carrier is 50%. An affected male has a 100% chance of having carrier daughters and a 0% chance of having affected sons. In 1997, an X-linked recessive form of laterality sequence caused by mutations in *HTX1* located on the long arm of the X chromosome (Xq26.2) was described. In the same year, it was determined that the gene is a zinc finger protein, and it was named *ZIC3*. The gene is known as both *ZIC3* and *HTX1*. *ZIC3* is involved in the development of the left-right axis, and mutations account for approximately 1% of individuals affected by heterotaxy. Accordingly, mutations in *ZIC3* cause inability of the embryo to establish normal left-right asymmetry.

Demographics

Laterality sequence defects occur in about 1 in every 8,500–25,000 live births. It occurs in individuals of all ethnic backgrounds. An equal number of males and females are affected by laterality sequence defects.

Signs and symptoms

Different laterality sequence defects can be described by the positioning of the various organs and associated malformations.

KEY TERMS

Complete situs inversus—A laterality defect resulting in a mirror image of the normal organ formation with heart, spleen, and stomach on the right side, and the liver and gallbladder on the left.

Dextrocardia—Right-sided positioning of the heart.

Heterotaxy—Random organ positioning in an individual that can result in multiple malformations with severe heart defects, livers found in the middle of the body, spleen abnormalities, and intestines turned in the opposite direction from normal (gastrointestinal malrotation).

Left-right axis—The developmental feature in a fetus that determines which side of the body is left and which side is right; it conducts the location and positioning of the fetus's internal organs.

Situs solitus—Normal organ placement in the body with the heart, stomach, and spleen placed toward the left, and the liver and gallbladder on the right.

Complete situs inversus or situs transversus is a laterality defect resulting in a mirror image of the normal organ formation with heart, spleen, and stomach on the right side and the liver and gallbladder on the left side. The normal pulmonary anatomy is reversed so that the left lung has three lobes and the right lung has two lobes. The remaining internal structures also are a mirror image of the normal.

Heterotaxy or situs ambiguous refers to random positioning of individual organs that can result in multiple malformations with severe heart defects, livers found in the middle of the body, spleen abnormalities, and intestines turned in the opposite direction than is standard (gastrointestinal malrotation). Often, structures normally found on one side of the body are duplicated or absent. Two primary subtypes of heterotaxy are based on the presence or absence of certain organs. In classic right isomerism, or asplenia, patients have a right atrium on both sides of the body, a centrally located liver, no spleen, and three lobes in both lungs. In left isomerism, or polysplenia, patients have left atria on both sides, multiple spleens, and two lobes in both lungs.

Dextrocardia refers to right-sided positioning of the heart. There are various forms of dextrocardia, ranging from a normally configured heart that is positioned farther to the right than normal to mirror-image dextrocardia, in which the positions of the heart chambers and major vessels are exactly the reverse of the standard arrangement.

Laterality sequence defects caused by mutations in *DNAH11* are characterized by situs inversus viscerum; intrauterine growth retardation; congenital heart defects, such as transposition of the great vessels, ventricular septal defect, atrial septal defect, truncus communis, and dextrocardia; right pulmonary isomerism; and right spleen. Mutations in *DNAH11* may also be associated with Kartagener syndrome, which includes bronchiectasis, sinusitis, dextrocardia, and infertility.

Laterality sequence defects caused by mutations in *CFC1* result in visceral heterotaxy, including a variable group of congenital anomalies that include complex cardiac malformations and situs inversus or situs ambiguous.

Laterality sequence defects caused by mutations in *ZIC3* include a variable group of congenital anomalies that include complex cardiac malformations (corrected transposition of great arteries, ventricular septal defect, and patent ductus arteriosus), dextrocardia, situs inversus, asplenia, polysplenia, situs inversus viscerum, pulmonic stenosis, and poor growth (intrauterine growth retardation). Some individuals with mutations in *ZIC3* have been found to have isolated heart defects only. Female carriers have been described with uterine septums and hypertelorism (wide-spaced eyes).

Diagnosis

Laterality defects may be discovered before birth and in infancy because of associated heart defects or other health problems. Laterality defects may remain asymptomatic in childhood and are discovered by chance in adult life as affected individuals seek medical attention for an unrelated condition. Clinical testing for many of the genes associated with laterality defects is available; however, diagnosis is still primarily based on imaging through means such as ultrasound, magnetic resonance imaging (MRI), and computed tomography (CT) scan.

Some symptoms of laterality sequence defects such as heart defects, poor growth (intrauterine growth retardation), and possibly organ reversal may be identified through a screening ultrasound around 18 weeks gestation of pregnancy. Accuracy of diagnosis of laterality sequence defects depends on the position, size, and maturity of the fetus, as well as an adequate volume of amniotic fluid and mother's size. A fetal echocardiogram can also help characterize a heart defect or placement before birth. If there is a known gene mutation present in an affected family member, prenatal diagnosis may be available through tests, such as amniocentesis.

QUESTIONS TO ASK YOUR DOCTOR

- Will my child require any operations to treat this condition?
- What form of laterality sequence does my child have?
- What are the chances of having another affected child?
- Are all forms of laterality sequence genetic?
- What types of medical complications will my child have as he or she gets older?
- Will my child's lifespan be shortened because of this diagnosis?

Diagnosis of a laterality sequence defect in infancy is most often made as a result of a heart defect or other serious medical issue related to the organ positioning and/or number of organs. Laterality sequence defects can be verified through use of x-rays, ultrasound, or CT scan. The location and relationships of the abdominal organs, veins of the liver, heart arteries and veins, heart chambers, and heart valves should be reviewed carefully.

Diagnosis in adulthood is based on clinical manifestations and exams such as abdominal and thoracic radiography and electrocardiogram. CT is the preferred examination for definitive diagnosis of situs inversus with dextrocardia because it provides good detail for confirming visceral organ position, cardiac position, and great vessel branching. MRI is usually reserved for difficult cases or for patients with associated cardiac anomalies. The features of laterality sequence defects are variable and require thorough evaluation of the internal organs for full diagnosis.

Treatment and management

The treatment and management of laterality sequence defects depend on the type of defect. Infants and children with laterality defects can have congenital heart defects and other associated birth defects that require surgery. Many adults with incidental detection of their laterality sequence anomalies do not need special treatment or management unless they are ill or need surgery. The recognition of situs inversus is important for preventing surgical mishaps that result from the failure to recognize reversed anatomy or an atypical history. The reversal of the organs may lead to some confusion, as many signs and symptoms are opposite from the standard side. Laterality sequence defects can also complicate

organ transplantation operations, as donor organs most likely come from normal individuals whose organs and vessels are a mirror image of the transplanted patients'. Accordingly, in the event of a medical problem, the knowledge that the individual has a laterality defect can increase the time and accuracy of diagnosis and increase the safety of surgery.

Prognosis

Many patients with laterality sequence defects such as total situs inversus present with no significant medical problems and have normal life expectancy. Total organ reversal results in normal relationships between the left-right positions of the organs and their blood supplies. In other forms of laterality sequence defects, such as those associated with Kartagener's syndrome, issues such as chronic respiratory problems and infertility can occur. Infants affected by complex cardiac defects may die as a result of their congenital heart defects. Prognosis in isolated dextrocardia depends on the congenital cardiac defects present. Women have been described with a uterine septum that can result in difficulties maintaining a pregnancy.

Leber congenital amaurosis

Definition

Leber congenital amaurosis (LCA) is a group of autosomal recessive-inherited eye disorders that lead to blindness at birth or within the first few years of life. Other manifestations of the disease may include hearing loss, intellectual disability, and decreased physical coordination.

Description

Vision is an important and complex sense by which the qualities of an object, such as color, shape, and size, are perceived through the detection of light. For proper vision, a critical series of biological steps must occur; if any of the steps in the process is abnormal, visual impairment or blindness may occur.

The process of vision begins with light that bounces off an object and passes through the outer coverings and lens of the eye and projects onto a layer of cells at the back of the eye called the retina. The retina contains two kinds of specialized cells types, called the rods and cones, that are responsible for sensing visual stimuli. When rods and cones are stimulated by light, impulses are conducted through the optic nerve to a region in the back of the brain known as the occipital lobe. The occipital lobe contains the visual cortex, the area of the brain that processes visual stimuli and integrates signals sent by the retina to obtain a composite image of an object.

Leber congenital amaurosis is the term for a group of inherited conditions in which the rod and cone receptors in the retina are defective or missing. Without the proper function of these specialized cells, light cannot be sensed normally.

LCA is often referred to by other names, such as congenital absence of the rods and cones, congenital retinal blindness, congenital retinitis pigmentosa, Leber congenital tapetoretinal degeneration, or Leber congenital tapetoretinal dysplasia. The disorder was first described in

1869 by the German ophthalmologist Theodor Leber, who subsequently showed that it was an inherited defect. Although similarly named, LCA should not be confused with another disorder of sight, Leber optic atrophy, which was also first described by Theodor Leber.

Genetic profile

Mutations in any one of at least 14 different genes may result in LCA. Each of the known genes produces proteins, which are located within the retinal rod and cone cells. These proteins participate in the detection of an incoming stimulus of light and the subsequent transmission of signals out of the retinal cells to the visual cortex of the brain. Six identified mutations likely account for less than half of all diagnosed cases of LCA; thus, there are additional mutations resulting in LCA that remain to be identified.

The most common genes associated with LCA are *RPE65*, *CEP290*, *CRB1*, and *GUCY2D*. Mutations in the genes *CRX* and *IMPHD1* also cause LCA, but as autosomal dominant mutations. Approximately 30% of LCA cases are due to unknown causes, and because so many genes are associated with LCA and the symptoms are so variable, it is very difficult to test for the disease.

LCA is a genetic condition and can be inherited or passed on in a family. The genetic defects for the disorder are all inherited as autosomal recessive traits, meaning that two mutant genes of the same group are needed to display the disease. A person who carries one mutant gene does not display the disease and is called a carrier. A carrier has a 50% chance of transmitting the gene to his or her children, who must inherit the same defective gene from each parent to display the disease. Since there are different genes that are responsible for causing LCA, two individuals with different types of LCA will have an unaffected child, as it is impossible for the child to inherit two of the same type of defective genes from his or her parents.

Location of genetic abnormality for specific types of Leber congenital amaurosis

Type	Abnormal	Mutant gene	Gene location
LCA1	Retinal-specific guanylate cyclase	RETGC/GUC2D	17p13.1
LCA2	Retinal pigment epithelium specific protein	RPE65	1p31
LCA3	Unknown	Unknown	14q24
LCA4	Arlhydrocarbon-interacting protein-like 1	AIPL1	17p13.1
LCA5	Unknown	Unknown	6q11-q16
LCA due to CRX defect	Cone-rod homeobox protein	CRX	19q13.3

(Gale)

Demographics

Although LCA affects approximately 1 in 80,000 people, it is considered one of the most common causes of childhood blindness. It can affect males and females equally. LCA has been reported to account for at least 5% of all cases of inborn blindness, but several reports suggest that is an underestimation. In 1957, scientific investigators reported that one form of LCA was responsible for 10% of blindness in Sweden. Several years later, similar rates of LCA were found in people living in the Netherlands. While this suggests that the geographical distribution of LCA is not uniform and may be higher in certain ethnic groups, a comprehensive study has never been performed.

Signs and symptoms

Because there are 13 types of LCA, there is considerable variation in the symptoms experienced by an affected infant. Most infants with LCA are often blind at birth or lose their sight within the first few years of life; however, some people with LCA may have residual vision. In these patients, visual acuity is usually limited to the level of counting fingers or detecting hand motions or bright lights, and patients are extremely farsighted. There may be some small improvement in vision during the first decade of life as the visual system reaches maturity, but it is uncommon for children to be able to navigate without assistance or to be able to read print.

Other symptoms of LCA may include crossed eyes, sluggish pupils, rapid involuntary eye movements, unusual sensitivity to light, and the clouding of the lenses of the eyes. Many children with LCA habitually press on their eyes with their fists or fingers. This habitual pressing on the eyes is known as an oculo-digital reflex and may represent an instinctual attempt to provide the developing visual cortex of the brain with a stimulus to replace the loss of normal visual stimuli. As a result of this behavior, the eyes may become thin and conical in shape and appear sunken or deep. In some cases, LCA is associated with hearing loss, epilepsy, decreased coordination, kidney problems, or heart abnormalities. Intellectual disability is present in approximately 20% of individuals affected with LCA.

Diagnosis

Infants are usually brought to medical attention within the first six months of life when parents notice a lack of visual responsiveness and the unusual roving eye movements characteristic of the disease. As with any evidence of loss of vision, a prompt and thorough evaluation is initiated to determine the cause of the visual defect, and steps may include physical tests designed to measure

KEY TERMS

Autosomal recessive—A pattern of genetic inheritance in which two abnormal genes are needed to display the trait or disease.

Braille—An alphabet represented by patterns of raised dots that are felt with the fingertips. It is the main method of reading used by the blind.

Carrier—A person who possesses a gene for an abnormal trait without showing signs of the disorder. The person may pass the abnormal gene on to offspring.

Computed tomography (CT) scan—An imaging procedure that produces a three-dimensional picture of organs or structures inside the body, such as the brain.

Electroretinography (ERG)—A diagnostic test that records electrical impulses created by the retina when light strikes it.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Occipital lobe—An anatomical subdivision, located at the back of the brain, that contains the visual cortex.

Oculo-digital reflex—A reflex causing an individual to press on his or her eyes with fingers or fists.

Retina—The light-sensitive layer of tissue in the back of the eye that receives and transmits visual signals to the brain through the optic nerve.

Visual cortex—The area of the brain responsible for receiving visual stimuli from the eyes and integrating it to form a composite picture of an object.

brain and eye function, CT scans (a method using x-rays controlled by a sophisticated computer) of the brain and eye, and even tests to look for genetic and metabolic causes of blindness.

Eye examinations of infants with LCA usually reveal a normal-appearing retina. By early adolescence, however, various changes in the retinas of patients with LCA become readily apparent; blood vessels often become narrow and constricted, and a variety of color changes can occur in the retina and its supportive tissue.

One of the most important tests in diagnosing LCA is called electroretinography (ERG). This test measures electrical impulses that are produced in the retina when

light is sensed by the rod and cone cells. It is useful in distinguishing whether blindness is due to a problem in the retina versus a problem in the visual cortex of the brain. When ERG tests are performed on people with LCA, there is no recordable electrical activity arising from the eye, indicating that the problem is based in the retina rather than in the brain.

Thus, an absence of activity on ERG, combined with the absence of diagnostic signs of other conditions that result in blindness, point to a diagnosis of LCA. Although several abnormal genes have been identified as responsible for LCA, genetic analysis and prenatal diagnosis is rarely performed outside of research studies.

Treatment and management

Currently, there is no treatment for LCA; thus, patient and family education and adaptive assistance is critical. Some people with remaining vision may benefit from vision-assistance technology such as electronic, computer-based, and optical aids, but severely visually impaired individuals often utilize traditional resources such as canes and companion-guide dogs. Orientation and mobility training, adaptive training skills, job placement, and income assistance are available through hospital physical and occupational therapy programs and various community resources. It should be noted that up to 20% of patients with LCA may have associated intellectual disability and require additional adaptive and vocational assistance.

Most people with LCA are unable to read print and instead utilize Braille, an alphabet represented by raised dots that can be felt with the fingertips. People with LCA often attend schools specially designed to meet the needs of visually impaired students and may require modifications to their home and work environments in order to accommodate their low or absent vision. Because almost all patients with LCA are legally blind, they are not able to drive or operate heavy machinery. Genetic counseling may assist affected individuals with family planning.

Scientists have several isolated mutant genes that can each cause LCA. Ongoing scientific research is directed toward understanding how these genes function in the retina and toward locating the remaining genes that cause LCA. With this information, scientists can better develop a means of prevention and treatment.

Gene Therapy

There has been some success in the treatment of LCA with the use of gene therapy. In 2008, a clinical trial reported on the safety and efficacy of introducing the

QUESTIONS TO ASK YOUR DOCTOR

- Relatives in my family have LCA—is it possible that I could be a carrier?
- My child has been diagnosed with LCA. What form of the disease does he or she have, and is there a course of treatment?
- Can I pass LCA to my children?

functional form of the human *RPE65* gene into the eyes of patients in whom LCA is caused by a mutation in the *RPE65* gene. In the three patients treated, no side effects were reported, and vision was improved for up to one and a half years.

In a 2009 study, 12 patients ranging in age from 8 to 44 with *RPE65* LCA were also treated with gene therapy to introduce a functional *RPE65* gene. They showed improvement, especially the younger patients.

In both of these trials, the adeno-associated virus (AAV) was used to introduce the *RPE65* gene, and there was some concern that antibodies made in the body against the AAV vector could compromise the treatment and the patients' health. In animal studies in which AAV antibodies were injected along with the AAV2-hRPE65v2, treatment did not show any complications. In later human trials, AAV antibody levels were measured and showed little to no change post treatment, suggesting that this form of gene therapy has little risk of producing harmful side effects.

A 2015 clinical study using gene therapy to treat 12 LCA patients with gene therapy to replace *RPE65* measured visual function three years after treatment and found no associated improvement that could be detected with ERG. The final conclusion was that gene therapy of LCA had mild effects on improving retinal sensitivity within the first 6–12 months, but that these effects were temporary.

Prognosis

While children born with LCA may have variable symptoms and differing levels of visual acuity, they can lead productive and healthy lives with adaptive training and assistance. In those patients who do not have associated problems with their brain, heart, or kidney, lifespan is approximately the same as in the general population; otherwise, the prognosis is variable and depends on the extent of the complication.

Leber hereditary optic atrophy

Definition

Leber hereditary optic atrophy is a painless loss of central vision (blurring of objects and colors appearing less vivid) that usually begins between the ages of 25 and 35 (but can occur at any age) and leads to legal blindness. Other minor problems may be present such as tremors, numbness or weakness in the arms and legs, or loss of ankle reflexes. It was first described in 1871 by Theodore Leber and is the most common cause of optic atrophy.

Description

Leber hereditary optic atrophy is also called Leber hereditary optic neuropathy or LHON. The beginning of visual blurring in both eyes is called the acute phase of LHON. In about half of patients, both eyes are

affected at the same time. In the remainder of patients, central vision is lost in one eye over a period of a few weeks, followed by the second eye a month or two later. Once both eyes are affected, a few weeks usually pass before the eyesight stops getting worse. Other less common patterns of central vision loss in LHON can be very sudden loss in both eyes, or very gradual loss occurring over several years. After the acute phase, there is rarely any significant change in eyesight during the remainder of the person's life. People with LHON are usually left with some peripheral vision, which is seeing around the edges, or out of the corner of the eye. This final phase is called the atrophic phase because the optic discs are atrophic (cells have wasted away) and rarely change.

The optic disc is the center part of the retina (back of the eye) and is where the clearest vision—both in detail and color—comes from. The retina interprets what a person sees, and sends this message to the brain, along the pathway known as the optic nerve. In LHON, both the retina and the optic nerve stop working properly. The rest of the eye works normally, so that light enters the eye through the pupil (black circle in the center of the iris, the colored part of the eye) as it should. However, in LHON patients, even though the light is focused on the retina properly, this information is not converted into signals for the brain to process. When a person wears prescription glasses, the purpose is to help focus light properly on the retina. In LHON, light is already focused as it should be, so glasses will not improve vision. Magnifying glasses and telescopes do help, however, because they make things look bigger. When a person looks through a magnifier or telescope, they use more of their retina to see, and some undamaged cells of the retina may be able to provide some information to the brain.

Suddenly losing vision can be a shock. Patients diagnosed with LHON may feel they have no useful sight left, and often, their family and friends treat them as the stereotypic blind person. In reality, LHON usually leaves an affected person with some useable vision. A variety of visual aids are available to enhance this.

Genetic profile

In 60% of patients with LHON, there is a positive family history of LHON, while the remaining cases are considered sporadic (occur by chance), where only one person in the family has LHON. In 1988, it was discovered that LHON is caused by a mutation in a mitochondrial gene. Mitochondria are the energy-producing organelles (structures) of cells. They have their own genetic material called mitochondrial DNA, which is separate from the usual genetic material contained in

KEY TERMS

Acute phase—The initial phase of LHON, when visual blurring begins in both eyes and central vision is lost.

Atrophic phase—The final phase of LHON where cells in the optic disc and optic nerve have atrophied, resulting in legal blindness. Peripheral vision remains.

Central vision—The ability to see objects located directly in front of the eye. Central vision is necessary for reading and other activities that require people to focus on objects directly in front of them.

Heteroplasmy—When all copies of mitochondrial DNA are not the same, and a mix of normal and mutated mitochondrial DNA is present.

Homoplasmy—When all copies of mitochondrial DNA are the same, or have the same mutation.

Leber hereditary optic atrophy or Leber hereditary optic neuropathy (LHON)—Discovered in 1871 by Theodore Leber, the painless loss of central vision in both eyes, usually occurring in the second or third decade of life, caused by a mutation in mitochondrial DNA. Other neurological problems, such as tremors or loss of ankle reflexes, may also be present.

Lifetime risk—A risk that exists over a person's lifetime; a lifetime risk to develop disease means that the chance is present until the time of death.

Mitochondria—Organelles within the cell responsible for energy production.

Mitochondrial inheritance—Inheritance associated with the mitochondrial genome that is inherited exclusively from the mother.

Multiple sclerosis (MS)—A progressive degeneration of nerve cells that causes episodes of muscle weakness, dizziness, and visual disturbances, followed by periods of remission.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Ophthalmologist—A physician specializing in the medical and surgical treatment of eye disorders.

Optic disc—The region where the optic nerve joins the eye; also referred to as the blind spot.

Optic nerve—A bundle of nerve fibers that carries visual messages from the retina in the form of electrical signals to the brain.

Peripheral vision—The ability to see objects that are not located directly in front of the eye. Peripheral vision allows people to see objects located on the side or edge of their field of vision.

Pupil—The opening in the iris through which light enters the eye.

Retina—The light-sensitive layer of tissue in the back of the eye that receives and transmits visual signals to the brain through the optic nerve.

Sporadic—Isolated or appearing occasionally with no apparent pattern.

the center of the cell (or nucleus). Each mitochondrion has several copies of its circular DNA. DNA is the chemical that makes up genes. Genes code for certain traits, and in some cases, can code for disease. Mutations in the DNA of a mitochondria may be present in all copies (called homoplasmy), or may be present in a portion of the mitochondria's DNA (called heteroplasmy). About 15% of individuals with LHON are heteroplasmic, which means some of their mitochondrial DNA has a mutation, and some does not. This may have a bearing on the chance to develop symptoms, and on the risk of transmission.

There are three specific DNA changes or mutations that are found in the majority (90%–95%) of LHON cases. The remaining LHON patients have other various mitochondrial mutations. In genetics, mutations are

designated in such a way as to tell a scientist where they are located in the mitochondrial DNA and what the DNA alteration is: for example, G11778A means the mutation is located at position 11778 and DNA change is G [guanine] to A [adenine], a change in the base pairs that make up DNA.

Not all persons who have one of these mutations will develop LHON, since it is thought that additional genetic or environmental factors are necessary to develop central vision loss. In general, males with one of these mutations have a 40% lifetime risk to develop symptoms of LHON, while females have a 10% risk, although the actual risk varies slightly from mutation to mutation. In addition, the older a person in whom a mutation has been identified becomes without symptoms, the less likely they will lose their vision at all. If a person is going to experience vision

loss from LHON, the majority of people with a mutation express symptoms by the age of 50 years.

Environmental factors that can reduce the blood supply to the retina and optic nerve and “trigger” the vision loss in LHON to begin include heavy drinking or smoking, exposure to poisonous fumes such as carbon monoxide, high levels of stress, and certain medications. A person in whom a mutation has been identified is considered more susceptible to some of these exposures and is advised not to smoke and to moderate their alcohol intake if they are asymptomatic.

The other important concept to understand in relation to mitochondrial disease is that mitochondria are only inherited from the mother. Therefore, a woman with a mitochondrial mutation (whether she has symptoms or not) will pass it to all of her offspring. Sons who inherit the mutation will not pass it to any of their children, while daughters who inherit the mutation will pass it to all of their children. This is in contrast to nuclear DNA, where half the genetic material is inherited from each parent.

Demographics

Males have LHON more often than females; however, females may develop LHON at a slightly older age and may have more severe symptoms, including a multiple sclerosis-like illness. Multiple sclerosis is a progressive degeneration of nerve cells that causes episodes of muscle weakness, dizziness, and visual disturbances, followed by remission. The onset of LHON usually occurs by age 50 if a mitochondrial DNA mutation is present, although it can present as late as the sixth or seventh decade of life.

Signs and symptoms

Symptoms of LHON include a painless sudden loss of central vision, in both visual detail and color, in both eyes over a period of weeks to months. Peripheral vision (seeing out of the corner of the eye) remains. Additional symptoms involving the neurological system may be present such as tremors, numbness or weakness in the arms or legs, or loss of ankle reflexes. Symptoms vary by gender and type of mutation present. The following mutations are frequently identified and well understood:

- G11778A—the most common mutation and usually the most severe vision loss
- T14484C—usually has the best long-term prognosis or outcome
- G3460A—has an intermediate presentation

Persons who have a multiple sclerosis-like illness can have any of the three mutations. This phenomenon—where different mutations give different

clinical outcomes—is called a genotype-phenotype correlation. The word *genotype* describes the specific findings in DNA, while the word *phenotype* is used to describe the clinical presentation.

Diagnosis

Suspicion of LHON is usually made by an ophthalmologist after a complete eye examination. Genetic testing for the presence or absence of mitochondrial mutations can then be performed from a small blood sample. After a symptomatic person with LHON in a family has been identified as having a mitochondrial mutation, other asymptomatic at-risk relatives can also be tested. At-risk relatives include the affected persons’ mother, siblings, and the offspring of any females found to have the mutation. Testing for asymptomatic children who are at risk is not currently offered since no treatment is available for LHON; these individuals could opt for testing upon becoming a legal adult (i.e., reaching 18 years of age). Prenatal diagnosis for LHON was as of 2021 not available in the United States, but may be offered elsewhere. With genetic testing for LHON, it is important to remember that the presence of a mitochondrial mutation does not predict whether the condition will occur at all, the age at which it will begin, the severity, or the rate of progression.

Treatment and management

There is no proven treatment available for LHON, although some studies report benefit from various vitamin therapies or other medications. Management of LHON is supportive, utilizing visual aids such as magnifiers.

Prognosis

The loss of central vision tends to remain the same (legally blind) over a lifetime once a person with LHON has reached the atrophic phase.

Leigh Syndrome

Definition

Leigh syndrome is a rare inherited neurometabolic disorder characterized by degeneration of the central nervous system (CNS; brain, spinal cord, and optic nerve), meaning that the CNS gradually loses its ability to function properly.

Description

First described in 1951, Leigh syndrome is usually diagnosed between the ages of three months and two years. The disorder worsens rapidly; the first signs may be loss of head control, poor sucking ability, and loss of previously acquired motor skills, meaning that the control of particular groups of muscles. Loss of appetite, vomiting, seizures, irritability, and/or continuous crying may accompany these symptoms. As the disorder worsens, other symptoms such as heart problems, lack of muscle tone (hypotonia), and generalized weakness may develop, as may lactic acidosis, a condition by which the body produces too much lactic acid. These symptoms eventually result in death. In rare cases, Leigh syndrome may begin late in adolescence or early adulthood, and in such cases, the progression of the disease is slower than with the classical form.

Leigh syndrome usually develops in three stages. The first is between eight and 12 months and involves vomiting and failure to thrive. The second is in infancy,

characterized by loss of motor ability, eye problems, and respiratory irregularity. The third stage occurs between two and 10 years of age and is characterized by hypotonia and feeding difficulties. Several different types of genetic enzyme defects are thought to cause Leigh syndrome, meaning that the disorder may be caused by defective enzymes, the proteins made by the body to speed up the biochemical reactions necessary to sustain life.

Commonly known as Leigh's disease, Leigh syndrome is also known as Leigh necrotizing encephalopathy, necrotizing encephalomyelopathy of Leigh's, and subacute necrotizing encephalopathy (SNE). When it occurs in adolescence and adulthood, it may be called adult-onset subacute necrotizing encephalomyelopathy.

Genetic profile

Leigh syndrome can be caused by mutations in one of more than 75 different genes. In most cases, Leigh syndrome is inherited as an autosomal recessive genetic trait. However, X-linked recessive, autosomal dominant, and mitochondrial inheritance can also occur. Several different types of genetic metabolic defects are thought to lead to Leigh syndrome. A deficiency of one or a number of different enzymes may be the cause.

Classic Leigh syndrome

The usual form of Leigh syndrome is inherited as an autosomal recessive genetic trait. The syndrome has been linked to multiple defects in the genes that cause either a deficiency of the enzyme pyruvate dehydrogenase or an abnormality in other enzymes that make pyruvate dehydrogenase work. Other cases of autosomal recessive Leigh syndrome are associated with other genetic enzyme deficiencies (i.e., NADH-CoQ and cytochrome C oxidase). All of these different genetic defects seem to have a common effect on the central nervous system.

In autosomal recessive inheritance, a single abnormal gene on one of the autosomal chromosomes (one of the 22 nonsex chromosomes) from both parents can cause the disease. Both of the parents must be carriers in order for the child to inherit the disease, but neither of the parents will have the disease (since it is recessive).

A child whose parents are carriers of the disease has a 25% chance of having the disease; a 50% chance of being a carrier of the disease, meaning that he or she is not affected by the disease but can pass the defective gene on to future children; and a 25% chance of receiving both normal genes, one from each parent, and being genetically normal for that particular trait.

KEY TERMS

Apnea—An irregular breathing pattern characterized by abnormally long periods of the complete cessation of breathing.

Ataxia—A deficiency of muscular coordination, especially when voluntary movements are attempted, such as grasping or walking.

Central nervous system (CNS)—In humans, the central nervous system is composed of the brain, the cranial nerves, and the spinal cord. It is responsible for the coordination and control of all body activities.

Enzyme—A protein that catalyzes a biochemical reaction or change without changing its own structure or function.

Hypotonia—Low or poor muscle tone, resulting in floppy limbs.

Lactic acidosis—A condition characterized by the accumulation of lactic acid in bodily tissues. The cells of the body make lactic acid when they use sugar as energy. If too much of this acid is produced, the person starts feeling ill with symptoms such as stomach pain, vomiting, and rapid breathing.

Metabolism—The total combination of all of the chemical processes that occur within cells and tissues of a living body.

Mitochondria—Organelles within the cell responsible for energy production.

Motor skills disorder—A disorder that affects motor coordination or its development and the control of particular groups of muscles that perform activities.

Necrosis—Death of a portion of tissue differentially affected by disease or injury.

Neurometabolic disorder—Any disorder or condition that affects both the CNS and the metabolism of the body.

X-linked Leigh syndrome

Evidence exists for an X-linked recessive form of Leigh syndrome, which has been linked to a specific defect in a gene called *E1-alpha*, a part of the enzyme pyruvate dehydrogenase.

X-linked recessive disorders are conditions that are coded on the X chromosome. All humans have two chromosomes that determine their biological sex: females have XX, and males have XY. X-linked recessive (also called sex-linked) inheritance affects the genes located

on the X chromosome. It occurs when an unaffected mother carries a disease-causing gene on at least one of her X chromosomes. Because females have two X chromosomes, one from each parent, they are usually unaffected carriers. The X chromosome that does not have the disease-causing gene compensates for the X chromosome that does. Generally, for a woman to have symptoms of the disorder, both X chromosomes would have the disease-causing gene. That is why women are less likely than men to show such symptoms.

If a mother has a female child, the child has a 50% chance of inheriting the disease gene and being a carrier who can pass the disease gene on to her children. On the other hand, if a mother has a male child, he has a 50% chance of inheriting the disease-causing gene, because he has only one X chromosome. If a male inherits an X-linked recessive disorder, he is affected. All of his daughters will also be carriers.

Mitochondrial Leigh syndrome

Leigh syndrome may be inherited in some cases from the mother as a DNA mutation inside mitochondria. Hundreds of tiny mitochondria are contained in every human cell. They control the production of cellular energy and carry the genetic code for this process inside their own special DNA, called mitochondrial DNA (mtDNA). The mtDNA instructions from the father are carried by sperm cells, and during fertilization, these instructions break off from the sperm cell and are lost. All human mtDNA, therefore, comes from the mother. An affected mother passes it to all of her children, but only daughters can pass the mutation on to the next generation.

When mutations occur on mtDNA, the resulting defective genes may outnumber the normal ones. Until mutations are present in a significant percentage of the mitochondria, symptoms might not occur. Uneven distribution of normal and mutant mtDNA in different tissues of the body means that different organ systems in individuals from the same family may be affected, and a variety of symptoms may result in affected family members. In about 20% of people with Leigh syndrome, the cause is mtDNA mutations.

Adult-onset Leigh syndrome

In cases of adult-onset Leigh syndrome, the disorder may be inherited in yet another way, as an autosomal dominant genetic trait. In autosomal dominant inheritance, a single abnormal gene on one of the autosomal chromosomes (one of the 22 nonsex chromosomes) from either parent can cause the disease. One of the parents will have the disease (since it is dominant) and will be the carrier. Only one parent needs to be a carrier in order for

the child to inherit the disease. A child who has one parent with the disease has a 50% chance of also having the disease.

Demographics

Leigh syndrome is rare. Overall, it affects about one in 40,000 newborns; the rate is much higher in some sub-populations, including in the Faroe Islands and some areas of Quebec, Canada. The classic form of the disorder accounts for approximately 80% of cases and affects males and females in equal numbers. In both X-linked Leigh syndrome and adult-onset Leigh syndrome, almost twice as many males as females are affected.

Signs and symptoms

The symptoms of developmental delay, hypotonia, and lactic acidosis are present in almost all cases of Leigh syndrome. Other symptoms vary widely and include the following:

- **Respiratory:** Hyperventilation, breathing arrest (apnea), shortness of breath (dyspnea), and respiratory failure. Respiratory disturbance may occur in as many as 70% of cases.
- **Neurological:** Muscle weakness, clumsiness, shaking, failure of muscular coordination (ataxia), and seizures.
- **Ocular:** Abnormal eye movements, sluggish pupils, and blindness.
- **Cardiovascular:** Heart disease and malformation. In adult-onset cases, progression of the disease is slower than with the classical form.

Diagnosis

The diagnosis of Leigh syndrome is usually made by clinical evaluation and a variety of tests.

Advanced imaging techniques

The main body part affected is the nerve cells (gray matter) of the brain with areas of dead nerve cells (necrosis) and cell multiplication (capillary proliferation) in the lowest part of the brain (brain stem). A CT scan or magnetic resonance imaging of the brain may reveal these abnormalities. Cysts may be present in the outer portion of the brain (cerebral cortex) as well.

Laboratory testing

Biochemical findings are high levels of pyruvate and lactate in the blood and slightly low sugar (glucose) levels in the blood and cerebrospinal fluid (CSF), a clear fluid that bathes the brain and spinal cord. Laboratory tests may reveal high levels of acidic waste products in the blood, indicative of lactic acidosis, as well as high levels of

QUESTIONS TO ASK YOUR DOCTOR

- What are the changes that will occur in my child's body as a result of Leigh syndrome?
- What are the genetic causes of this disorder?
- What types of treatment are available for my child as he or she grows through infancy and childhood as a result of Leigh syndrome?
- How long do patients with Leigh syndrome typically live?

pyruvate and alanine. The enzyme pyruvate carboxylase may be absent from the liver. An inhibitor of thiamine triphosphate (TTP) production may be present in the blood and urine of affected individuals. Blood glucose may be somewhat lower than normal. Some children with the disorder may have detectable deficiencies of the enzymes pyruvate dehydrogenase complex or cytochrome C oxidase.

Related disorders

Symptoms of other disorders are very similar to those of Leigh syndrome, and comparisons may be useful to distinguish between them. These disorders are the following:

- Wernicke encephalopathy
- Kufs disease
- Batten disease
- Tay-Sachs disease
- Sandhoff disease
- Niemann-Pick disease
- Alpers disease

Prenatal testing

Genetic counseling may be beneficial for families with a history of Leigh syndrome. Prenatal testing is available to assist in prenatal diagnosis. Prior testing of family members is usually necessary for prenatal testing.

Either chorionic villus sampling (CVS) or amniocentesis may be performed for prenatal testing. CVS is a procedure to obtain chorionic villi tissue for testing. Examination of fetal tissue can reveal information about the changes that lead to Leigh syndrome. CVS can be performed at 10 to 12 weeks of pregnancy.

Amniocentesis is a procedure that involves inserting a thin needle into the uterus, into the amniotic sac, and

withdrawing a small amount of amniotic fluid. DNA can be extracted from the fetal cells contained in the amniotic fluid and tested. Amniocentesis is performed at 15 to 18 weeks of pregnancy.

Tissue obtained from CVS or in amniotic fluid that shows evidence of the genetic abnormalities responsible for Leigh syndrome confirms the diagnosis. Other forms of prenatal testing may be available for Leigh syndrome.

Treatment and management

The most common treatment for the disorder is the prescription of thiamine or vitamin B1. This may result in a temporary improvement of the symptoms and slightly slow the progress of the disease.

Patients who lack the pyruvate dehydrogenase enzyme complex may benefit from a high-fat, low-carbohydrate diet.

To treat lactic acidosis, oral sodium bicarbonate or sodium citrate may be prescribed. To control severe lactic acidosis, intravenous infusion of tris(hydroxymethyl)aminomethane (THAM) may be beneficial. Both treatments help reduce abnormally high acid levels in the blood and the accumulation of lactic acid in the brain.

If eye problems occur, the individual with Leigh syndrome may benefit from treatment from an ophthalmologist.

Treatment should include assistance with locating support resources for the family and the individual with Leigh syndrome.

Prognosis

Prognosis for individuals with classical Leigh syndrome is poor. Death usually occurs within a few years, although patients may live to be six or seven years of age. Some patients have survived to the mid-teenage years. Children who survive the first episode of the disease might not fully recover physically and neurologically. They are likely to face successive bouts of devastating illness that ultimately cause death.

In 2021, scientists used genetic engineering to develop a model for Leigh disease that allows them to reproduce some of the developmental effects of a specific gene mutation, *SURF1*. Although it is a long way from this model to a cure for Leigh syndrome, this is the first workable model that allows researchers to experiment with possible protective measures or gene therapy for the disorder.

Clinical trials for Leigh syndrome, including experimental drug treatments and procedures, are underway. Participation in a U.S. clinical trial is voluntary and at no cost to the participant. All clinical trials receiving

U.S. government funding, and some supported by private industry, are posted at <https://www.clinicaltrials.gov>. Foreign trials are listed at <https://www.orpha.net>

Lesch-Nyhan syndrome

Definition

Lesch-Nyhan syndrome (LNS) is a rare genetic disorder that primarily affects males. Males with this syndrome develop physical handicaps, behavioral symptoms, mental retardation, and kidney problems. LNS is caused by a total absence of a purine-recycling enzyme known as hypoxanthine-guanine phosphoribosyltransferase. Self-injury is a classic feature of this genetic disease.

Lesch-Nyhan syndrome: pedigree analysis chart (Gale)

Description

Lesch-Nyhan syndrome was first described in 1964 by two American physicians, Dr. Michael Lesch and Dr. William Nyhan; its biochemical cause was identified in 1967. The syndrome is caused by a severe change (mutation) in the *HPRT1* gene. This gene is responsible for the production of an enzyme called hypoxanthine-guanine phosphoribosyltransferase (HPRT), which catalyzes a reaction necessary to prevent the buildup of uric acid. The enzyme enables cells to recycle purines, which are organic molecules critical to the structure of both DNA and RNA. A number of mutations in the *HPRT1* gene result in the absence or very low levels of HPRT enzyme activity, which in turn leads to markedly elevated uric acid levels in the blood—a condition called hyperuricemia. This buildup of uric acid is toxic to the body and is related to the symptoms associated with the disease. Absence of HPRT enzyme activity is also thought to alter the chemistry of certain parts of the brain, including the basal ganglia, affecting neurotransmitters (chemicals used for communication between nerve cells), acids, and other chemicals. This change in the nervous system is also related to the symptoms associated with Lesch-Nyhan syndrome.

Males with Lesch-Nyhan syndrome develop neurological problems during infancy. Infants with Lesch-Nyhan syndrome have weak muscle tone (hypotonia) and are unable to develop normally. Affected males develop uncontrollable writhing movements (athetosis) and muscle stiffness (spasticity) over time. Lack of speech is also a common feature of Lesch-Nyhan syndrome. The most dramatic symptom of Lesch-Nyhan syndrome, however, is the compulsive self-injury seen in 85% of affected males. This self-injury does not indicate that patients with LNS are insensitive to pain. The self-mutilating behavior involves the biting of the

patient's own lips, tongue, and fingertips, as well as head banging. These behaviors may lead to serious injury and scarring.

Some boys with LNS develop a rare blood disorder known as megaloblastic anemia, which results from impairment of DNA synthesis during the production of red blood cells. In this form of anemia, the red blood cells grow larger without dividing, resulting in enlarged but dysfunctional blood cells in the bone marrow, a lower than normal red blood cell count in the bloodstream, and low hemoglobin levels.

LNS is a disorder with some phenotypic variability even in the same family; some patients are only mildly impaired, have normal intelligence, and do not always manifest self-injurious behaviors while others show profound developmental delays with muscle contractures and progressive loss of kidney function. The overall severity of the disorder depends on the way in which the mutations in the *HPRT1* gene affect the activity levels of the HPRT enzyme. There are more than 615 mutations in the *HPRT1* gene that had been identified as of 2015.

There is a less severe genetic disorder related to LNS called Kelley-Seegmiller syndrome or HPRT-related gout; it is also caused by mutations in the *HPRT1* gene. This syndrome involves only partial deficiency (at least 8% of normal levels) of the HPRT enzyme rather than a complete lack of it. People with Kelley-Seegmiller syndrome typically suffer from gout and kidney stones but do not have the neurological symptoms associated with LNS.

A third group of patients, with mutations in the *HPRT1* gene that result in HPRT enzyme levels between 1.5% and 8% of normal, develop a milder form of LNS called HPRT deficiency, neurologic variant. This condition is marked by uric acid overproduction and neurological symptoms that may range from simple clumsiness in voluntary movements to major muscular dysfunction.

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman’s abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Athetosis—A condition marked by slow, writhing, involuntary muscle movements.

Basal ganglia—A group of nuclei (specialized clumps of cells) at the base of the forebrain responsible for control of voluntary muscle movement.

Chorea—Involuntary rapid or jerky movements.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted either through the mother’s vagina or abdominal wall and a sample of cells is collected from around the fetus. These cells are then tested for chromosome abnormalities or other genetic diseases.

Enzyme—A protein that catalyzes a biochemical reaction or change without changing its own structure or function.

Hypotonia—A condition marked by poor muscle tone, often accompanied by low muscle strength. Hypotonia in infants is sometimes called “floppy baby syndrome.”

Lithotripsy—A procedure for treating kidney stones that involves the use of external shockwaves to break down the stones into small pieces that can be passed in the patient’s urine.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Neurotransmitter—Chemical in the brain that transmits information from one nerve cell to another.

Palsy—Uncontrollable tremors.

Purines—A group of organic compounds that are important building blocks of RNA and DNA. Two of the four nucleobases found in DNA (adenine and guanine) are purines.

Spasticity—Increased muscle tone or stiffness, which leads to uncontrolled and awkward movements.

Genetic profile

Mutations in the *HPRT1* gene, which is located on the long arm of the X chromosome at Xq26.1, are responsible for deficient activity of the HPRT enzyme (less than 1.5% of normal levels in patients with full-blown LNS). There have been many different mutations identified in the *HPRT1* gene. These mutations may differ in severity within the same family. Because the *HPRT1* gene is located on the X chromosome, Lesch-Nyhan syndrome is considered an X-linked disorder and affects only males.

A person’s sex is determined by their chromosomes. Males have one X chromosome and one Y chromosome; females have two X chromosomes. Males who possess a severe mutation in the *HPRT1* gene on their single X chromosome will develop Lesch-Nyhan syndrome.

Females who possess a mutation in one of their *HPRT1* genes will not develop LNS; instead, they are carriers. This difference is due to the fact that most females have another X chromosome without the mutation that prevents them from getting the disease. If a woman is a carrier, she has a 50% risk with each pregnancy to pass on her copy of the X chromosome with the mutation.

She has a 25% risk of giving birth to an affected son, a 25% risk of having a carrier daughter, a 25% chance of having an unaffected son, and a 25% chance of having an unaffected daughter. Males with LNS do not pass on their defective X chromosome because they do not reproduce due to the characteristics of the disease.

Demographics

Lesch-Nyhan syndrome affects approximately 1 in 380,000 live births. It occurs among members of all races and ethnic groups. Almost always, only male children are affected. Women carriers usually do not have any symptoms in childhood or adolescence. Women carriers occasionally develop inflammation of the joints (gout) as they get older.

Signs and symptoms

LNS is not usually diagnosed until the affected child shows signs of developmental delay or self-inflicted injuries. At birth, males with Lesch-Nyhan syndrome appear completely normal. Development is usually normal for the first few months. Symptoms develop between three

to six months of age. Sand-like crystals of uric acid in the baby's diapers may be one of the first symptoms of the disease. The baby may be unusually irritable. Typically, the first sign of nervous system impairment is hypotonia, often reflected in the baby's inability to lift the head or sit up at an appropriate age. Many patients with Lesch-Nyhan never learn to walk. By the end of the first year, writhing motions (athetosis), and spasmodic movements of the limbs and facial muscles (chorea) are clear evidence of defective motor development.

The compulsive self-injury associated with Lesch-Nyhan syndrome begins on average at three years of age. The self-injury begins with biting of the lips and tongue. As the disease progresses, affected individuals frequently develop finger biting and head banging. The self-injury can increase during times of stress.

Males with Lesch-Nyhan disease may develop kidney damage due to kidney stones. Blood in the urine (hematuria) is another frequent sign of LNS. Swollen and tender joints (gout) are another common problem.

Diagnosis

The diagnosis of Lesch-Nyhan syndrome is based initially on the distinctive pattern of symptoms. Measuring the amount of uric acid in a person's blood or urine cannot definitively diagnose Lesch-Nyhan syndrome. It is diagnosed by measuring the level of activity of the HPRT enzyme through a blood test called an enzyme assay. When the activity of the enzyme is very low, it is diagnostic of Lesch-Nyhan syndrome. LNS can also be diagnosed by molecular testing. This is also a blood test. Molecular genetic testing checks for changes (mutations) in the *HPRT1* gene. Results from DNA testing are not only helpful in making the diagnosis but may also serve to guide the family's decisions about future pregnancies. Both enzyme assays and molecular genetic testing for mutations in the *HPRT1* gene were readily available in North America and Europe as of 2015.

Prenatal diagnosis is possible by DNA testing of fetal tissue drawn by amniocentesis or chorionic villus sampling. Fetuses should be tested if the mother is a known carrier of a mutation in her *HPRT1* gene. A woman is at risk of being a carrier if she has a son with Lesch-Nyhan syndrome or if someone in her family has Lesch-Nyhan syndrome. Any woman who may be a carrier should have DNA testing.

Treatment and management

There are no known treatments for the neurological defects of Lesch-Nyhan. A medication called allopurinol

QUESTIONS TO ASK YOUR DOCTOR

- What genetic changes in my son's body are responsible for his Lesch-Nyhan syndrome?
- What changes in my son's physical and mental conditions resulting from his Lesch-Nyhan syndrome are likely to occur as he grows older?
- How can we control my son's self-destructive behaviors that result from Lesch-Nyhan syndrome?
- What is the probability of our having a second child with Lesch-Nyhan syndrome?

(Zyloprim) can lower blood uric acid levels but does not affect the behavioral problems and developmental delays. Drugs that are used to relieve the neurological symptoms in patients with LNS include haloperidol (Haldol), diazepam (Valium), lorazepam (Ativan), and phenobarbital (Luminal). Muscular symptoms may be treated with baclofen (Lioresal).

Patients with LNS who develop kidney stones may be treated with lithotripsy, a procedure that uses shock waves to break down kidney stones into pieces small enough to pass in the urine.

Some patients with Lesch-Nyhan syndrome have their teeth removed to prevent self-injury. Restraints are recommended to reduce self-destructive behaviors.

Prognosis

With strong supportive care, infants born with Lesch-Nyhan can live into their early 30s with symptoms continuing throughout life; however, many patients die in the first decade of life. Few live beyond age 40.

At present, there are no preventive measures for Lesch-Nyhan syndrome. However, recent studies have indicated that this genetic disorder may be a good candidate for treatment with gene replacement therapy. Unfortunately, the technology necessary to implement this therapy did not exist as of 2015.

Leukodystrophy

Definition

Leukodystrophy is a collection of about 15 rare genetic disorders that affect the brain, spinal cord, and peripheral nerves. It is characterized by abnormal growth or development of the white matter covering nerve fibers in the brain.

Description

Leukodystrophy comes from the Greek words "leuko" meaning "white" (referring to the white matter of the nervous system) and "dystrophy" meaning "abnormal growth or development." The white matter is the myelin sheath and is an extremely complex substance composed of at least ten chemicals. The myelin sheath protects the axon (a long and single-nerve cell process that acts as a wire to conduct impulses away from the cell body) much the way insulation protects an electric wire.

Each type of leukodystrophy affects one of the chemicals that make up the myelin sheath. Leukodystrophies include Alexander's disease; childhood ataxia with

central nervous system hypomyelination (CACH), also known as vanishing white matter disease; cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL); cerebrotendinous xanthomatosis (CTX); metachromatic leukodystrophy; ovariroleukodystrophy syndrome; and Van der Knapp syndrome, also called vacuolating leukodystrophy with subcortical cysts, 4H leukodystrophy, and hereditary diffuse leukoencephalopathy with neuroaxonal spheroids (HDLS), which is an adult-onset leukodystrophy.

Additional leukodystrophies include adrenoleukodystrophy (ALD)/adrenomyeloneuropathy (AMN), Aicardi-Goutieres syndrome, canavan disease (spongy degeneration), Krabbe disease (globoid cell leukodystrophy), neonatal adrenoleukodystrophy, Pelizaeus-Merzbacher disease (X-linked spastic paraplegia), Refsum disease, and Zellweger syndrome.

Genetic profile

Genes are the blueprint for the human body that directs the development of cells and tissue. Mutations in some genes can cause genetic disorders such as leukodystrophy. Every cell in the body has 23 pairs of chromosomes, 22 pairs of which are called autosomes and contain two copies of individual genes. The twenty-third pair of chromosomes are called the sex chromosomes because they determine a person's sex. Males have an X and a Y chromosome, while females have two X chromosomes.

Most leukodystrophies have an autosomal recessive pattern of inheritance that affects males and females. This excludes HDLS, which is inherited in an autosomal dominant pattern. People with only one abnormal gene are carriers, but since the gene is recessive, they do not have the disorder. Their children will be carriers of the disorder but not show symptoms of the disease. Both parents must have one of the abnormal genes for a child to have symptoms of an autosomal recessive leukodystrophy. When both parents have the abnormal gene, there is a 25% chance that each child will inherit both abnormal genes and have the disease. There is a 50% chance that each child will inherit one abnormal gene and become a carrier of the disorder but not have the disease itself. There is a 25% chance that each child will inherit neither abnormal gene and not have the disease or be a carrier.

Mutations in specific genes that code for proteins that are crucial in the structure and function of the myelin sheath will cause leukodystrophy. Alexander's disease, for example, is due to a mutation in the *GFAP* gene that codes for a glial protein that acts to build the sheath

around the nerves. Vanishing white matter disease is due to a mutation in one or more of the genes *EIF2B1–EIF2B5*, all of which code for proteins that regulate the synthesis of other proteins. Van der Knapp syndrome, in 75% of cases, is due to a mutation in the *MLC1* gene, which also codes for a protein in glial cells of the brain, specifically astrocytes. In addition, metachromatic leukodystrophy is associated with a mutation in the *ARSA* gene, which is important for proteins necessary to break down lysosomes. Alterations of the *POLR3A* and *POLR3B* genes are associated with five types of leukodystrophies, including 4H leukodystrophy.

Demographics

Leukodystrophies appear to affect all racial and ethnic groups and all geographic populations. However, metachromatic leukodystrophy has been found in a higher frequency in highly inbred groups, such as the Habbanite Jewish population, and is reported in 1 in 40,000 to 1 in 160,000 people worldwide.

Signs and symptoms

The most common signs seen in most leukodystrophies include gradual changes in an infant or child who previously appeared healthy. These changes may appear in body tone, movements, gait, speech, the ability to eat, hearing, vision, behavior, and memory. Specific signs and symptoms for individual leukodystrophies include the following:

- Metachromatic, with the most common and most severe form occurring between the ages of six months and two years with symptoms such as irritability, decreased muscle tone, muscle wasting, and difficulty learning to walk and talk. Onset symptoms in older children and adults include deterioration of intellectual performance and behavioral or psychiatric problems. Blindness, seizures, and paralysis occur as the disease progresses.
- Alexander's disease, which usually begins in infancy (6 to 24 months of age), affects mostly males. Initial signs are physical retardation and intellectual disability, and as the disease progresses, enlargement of the brain and head, spasticity, and seizures. In children and adults, symptoms are the same but occur less frequently and progress more slowly.
- CACH is usually diagnosed in infancy, and initial symptoms include motor and speech difficulties that progressively worsen. Later symptoms include difficulty swallowing, seizures, and coma.
- CADASIL can be diagnosed in children and adults but usually shows up around age 45. The initial symptom is

KEY TERMS

Arteriopathy—Damage to blood vessels.

Ataxia—A deficiency of muscular coordination, especially when voluntary movements are attempted, such as grasping or walking.

Bile acids—Steroid acids such as cholic acid that occur in bile, an alkaline fluid secreted by the liver and passed into a part of the small intestine where it aids in absorption of fats.

Bile alcohol—A steroid acid with an alcohol group attached.

Cataract—A clouding of the eye lens or its surrounding membrane that obstructs the passage of light, resulting in blurry vision. Surgery may be performed to remove the cataract.

Dementia—A condition of deteriorated mental ability characterized by a marked decline of intellect and often by emotional apathy.

Hypomyelination—The death of myelin on a nerve or nerves.

Ischemic attack—A period of decreased or no blood flow.

Leukoencephalopathy—Any of various diseases, including leukodystrophies, affecting the brain's white matter.

Spasticity—Increased muscle tone, or stiffness, which leads to uncontrolled, awkward movements.

Subcortical infarcts—Obstruction of nerve centers below the cerebral cortex of the brain.

usually migraine headaches, followed in about ten years by ischemic attacks and small strokes then by mood disturbances and dementia. Epilepsy sometimes occurs.

- CTX may present initial symptoms of cataracts, mild intellectual disability, and fatty tumors (called xanthomas) in tendons, especially the Achilles tendon or heel cord. Later symptoms include seizures, emotional or psychiatric disturbances, and impaired motion or muscle movement.
- Ovarioleukodystrophy syndrome usually has onset symptoms of walking difficulties and/or intellectual disability.
- Van der Knapp syndrome can have onset at or shortly after birth with the symptom of an extremely enlarged head. Onset usually occurs between ages four and five with initial symptoms of cerebella ataxia followed by spasticity. Later symptoms include mental slowing and

learning problems and sometimes epileptic seizures and severe walking impairment.

Diagnosis

Leukodystrophies are occasionally misdiagnosed as muscular dystrophy, since they all are neurological disorders involving white matter. Genetic testing is usually necessary for all leukodystrophies. A nerve conduction velocity (NCV) test is sometimes used to evaluate nerve damage in people with metachromatic leukodystrophy. The NCV test sends small electrical shocks through one end of a nerve. The time it takes to travel to the other end of the nerve is measured to help determine the severity of nerve damage. Diagnosis of CTX is made by measuring the levels of bile alcohol in the blood or urine or of cholestanol in the blood. Cholestanol is similar chemically to cholesterol but can be distinguished from it by special chemical tests. MLD and Van der Knapp syndrome diagnosis are usually made by a brain imaging scan called magnetic resonance imaging. A series of biochemical tests is sometimes used to diagnose MLD.

Treatment and management

With the exception of CTX, none of the leukodystrophies covered here are treatable. In some of the disorders, specific symptoms can be treated. For example, some infections associated with MLD, such as pneumonia, can be treated with antibiotics. In ovarioleukodystrophy syndrome, ovarian insufficiency can be treated with hormone replacement therapy. However, there are no treatments available for most of the conditions associated with leukodystrophies, such as intellectual disability; dementia; deterioration of speech, vision, and mobility; and degeneration of myelin (white matter). In CTX, administration of certain bile acids, especially chenodeoxycholic acid, can prevent further progression of the disorder and in some cases may bring improvement.

Prognosis

The prognosis varies between leukodystrophy types, but overall most people with leukodystrophy can expect a shortened lifespan. Infants with Alexander's disease generally do not live past the age of five or six. Infants with MLD usually do not live past age 10. In children and adults, Alexander's disease and MLD progress more slowly but life expectancy is still shortened, roughly 10 years post onset. Life expectancy with CACH is also shortened, with few people living beyond age 40. CADA-SIL progresses slowly, but death occurs on average about 21–22 years after onset of symptoms. Life expectancy is closer to normal with CTX provided it is diagnosed and treated early. Ovarioleukodystrophy is a relatively newly

QUESTIONS TO ASK YOUR DOCTOR

- What type of leukodystrophy does my child have?
- What are the treatment options for my child?
- What are the chances that any of my future children will have a leukodystrophy, and is genetic testing available to us?
- What is the prognosis for my child?
- How can this be managed to improve the quality of life of my child?

identified disorder and there is not enough information available to make a prognosis of life expectancy other than to say it is probably reduced. The average life expectancy is also unknown for Van der Knapp syndrome; several patients have died in their 20s, but others are still alive in their 40s.

A number of government agencies and private foundations are currently funding research into many of the leukodystrophies, including identifying the cause of individual disorders, developing therapies to prevent disease progression, and preventing onset of disease. However, according to the Myelin Project, a private research foundation, little research is being done on therapies to repair damage already done by the disorders or to restore functions lost because of the disorders.

Li-Fraumeni syndrome

Definition

Li-Fraumeni syndrome (LFS) is a hereditary condition in which individuals have an increased risk of developing certain kinds of tumors. The characteristic tumors of LFS are adrenocortical carcinoma, breast cancer, brain cancer, leukemia, and sarcoma. Li-Fraumeni syndrome

was previously known as the sarcoma, breast, leukemia, and adrenal gland (SBLA) syndrome.

Description

Li-Fraumeni syndrome is an inherited condition that is associated with a significantly increased risk of developing certain kinds of cancer. It is classified as a hereditary cancer syndrome and was first described in 1969 by two American physicians, Frederick Pei Li (1940–) and Joseph F. Fraumeni, Jr. (1933–). Hereditary cancer syndromes typically result in multiple family members developing cancer, in family members developing the same kind(s) of cancer, in family members developing cancer at a young age, and in family members developing more than one primary cancer. In contrast, most people who develop cancer are diagnosed later in life, often in their 60s and 70s, and do not have multiple close family members, such as a

Li-Fraumeni syndrome: pedigree analysis chart (Gale)

parent and/or siblings, who have developed the same kind of cancer.

Five cancers are characteristic of LFS. These five cancers are adrenocortical carcinoma, breast cancer, brain cancer, leukemia, and sarcoma. Such other types of cancer as melanoma, colon cancer, and stomach cancer have been seen in families with LFS, but it is not certain whether these tumors are truly a part of LFS.

Adrenocortical carcinoma is a rare cancer affecting a specific part of the adrenal gland called the adrenal cortex. There are two adrenal glands, and each one sits on the upper part of a kidney. Adrenal glands produce hormones, and if a cancer is present, more hormones may be produced, resulting in symptoms. In LFS, adrenocortical carcinomas typically develop in childhood.

Brain cancer refers to a tumor developing in the brain. There are different kinds of tumors that may develop in the brain; the type depends upon the part of the brain involved. The brain tumors that occur in LFS tend to develop in young adulthood, although they may develop at any age.

Breast cancer is a cancer affecting the breast. In LFS, women are often diagnosed with breast cancer in their 20s, 30s, and 40s. Although breast cancer in men is rare, it does occur both within families with LFS and in the general population.

Leukemia refers to cancer of the blood. There is more than one type of leukemia; the type depends upon the kind of blood cell involved and whether the cancer is fast (acute) or slow (chronic) growing. Overall, acute lymphocytic leukemia (ALL) is the most common leukemia in children, and acute myelogenous leukemia (AML) is common in young adults. Chronic myelogenous leukemia (CML) is a common leukemia in older individuals. Li-Fraumeni syndrome is typically associated with acute leukemias and is most often diagnosed in children, adolescents, and young adults.

Sarcoma refers to a soft-tissue tumor, meaning that the tumor has developed in bone, muscle, or connective tissue. Osteosarcoma refers to a sarcoma that has developed in the bone. Rhabdomyosarcoma is a sarcoma that has developed in the muscle. Both of these sarcomas are associated with LFS and typically are diagnosed in children and in adults before the age of 35 years. A third type of sarcoma, Ewing’s sarcoma, is another type of sarcoma arising in bone, but it is not associated with LFS.

An individual inheriting the familial LFS gene alteration has a significantly increased risk of developing one of the five characteristic cancers in his/her lifetime. This risk is about 85%–90% by age 60, meaning that 85–90 out of 100 individuals inheriting a LFS gene

Age of onset for cancers associated with Li-Fraumeni syndrome	
Age of onset	Type of cancer
Infancy	Development of adrenocortical carcinoma
Under 5 years of age	Development of soft-tissue sarcomas
Childhood and young adulthood	Acute leukemias and brain tumors
Adolescence	Osteosarcomas
Twenties to thirties	Premenopausal breast cancer is common

(Gale)

alteration will develop one of the five characteristic cancers by the time he/she reaches 60 years of age. Much of this risk occurs in childhood through middle adulthood, with the majority of individuals developing cancer by the time they reach 30 years of age.

Genetic profile

Li-Fraumeni syndrome follows an autosomal dominant inheritance pattern, meaning that every individual diagnosed with LFS has a 50% chance of passing on the condition to each of his/her children. Nearly every individual inheriting the LFS gene alteration will develop at least one of the characteristic tumors. However, not every family member inheriting the LFS gene alteration will develop the same kind of tumor. Additionally, some family members may develop more than one tumor, whereas other family members may develop one tumor. For example, a family history may include a father who was diagnosed with a brain tumor at age 50, a daughter who was diagnosed with an adrenocortical carcinoma at age three and breast cancer at age 43 years, and a granddaughter who was diagnosed with sarcoma at age seven.

The majority of families with LFS have an alteration in the *TP53* gene located on the short arm of chromosome 17 at location 17p13.1. This gene codes for a protein that functions as a tumor suppressor. Mutations in the *TP53* gene that alter the tumor suppressor protein thus allow cells with damaged DNA to continue to reproduce, thus increasing the individual’s risk of developing tumors. Some cases of LFS, however, develop in individuals without a family history of the syndrome. Researchers estimate that between 7% and 20% of mutations in the *TP53* gene are *de novo* mutations.

Another gene that has recently been associated with Li-Fraumeni syndrome is the *CHEK2* gene on the long arm of chromosome 22 at 22q12.1. This gene codes for a protein that is also involved in DNA repair and the programmed death of damaged cells. As of 2015, several families with cancers characteristic of LFS have been identified with mutations in the *CHEK2* gene.

Researchers are not yet certain, however, whether mutations in this gene actually cause LFS or whether they simply increase the risk of developing the cancers typical of Li-Fraumeni syndrome.

Demographics

Li-Fraumeni syndrome is a rare condition. One American registry indicates that about 400 people from 64 families in the United States have LFS. About 400 families worldwide have been reported in the medical literature as of 2015; however, not all families with LFS have been reported in the medical literature. Males and females are equally affected. There was no evidence as of 2015 that certain races or ethnic groups are at greater risk of LFS than others.

Signs and symptoms

General symptoms of cancer include unexplained weight loss, weakness, fatigue, and pain. It should be noted that the same kind of cancer may cause different symptoms in different people. Individuals with LFS may develop other kinds of cancer; consequently, any new and/or unusual symptom should be evaluated by a physician.

Symptoms specific to each tumor are as follows: Adrenocortical carcinomas may cause abdominal pain. In some cases, the tumor causes extra hormones to be produced and, if so, the individual may experience high blood pressure, diabetes, deepening of the voice, swelling of the sexual organs and/or breasts, or growth of hair on the face. Brain cancer may result in a number of symptoms including vomiting, seizures, headaches, behavioral changes or problems, changes in eating or sleeping patterns, fatigue, or clumsiness. Breast cancer typically results in a lump in the breast. Occasionally, the nipple may invert, or the skin over the lump may dimple. In rare cases, the breast may suddenly become red and swollen. Breast cancer can be identified before symptoms develop by the use of mammography. Leukemia may result in unusual bruising, a pale appearance, and/or recurrent infections. Little red or purple spots called petechiae may develop on the skin. Sarcomas result in different symptoms depending upon the type of sarcoma. Osteosarcomas often lead to swelling and pain, symptoms that may be confused with an injury. Rhabdomyosarcomas cause a lump to develop and produce swelling.

Diagnosis

Evaluation of a family history for LFS requires a detailed three-generation family tree as well as medical records and/or death certificates to confirm or clarify the tissues involved as well as the age of the individual at

KEY TERMS

Chemotherapy—Treatment of cancer with synthetic drugs that destroy the tumor either by inhibiting the growth of the cancerous cells or by killing the cancer cells.

De novo mutation—A genetic mutation that is not inherited from either parent. The Latin phrase means “new.”

Mammography—X-rays of the breasts; used to screen for breast cancer.

Metastasis (plural, metastases)—The spreading of cancer from the original site to other locations in the body.

Primary tumor—The organ or tissue where the tumor began.

Protocol—A set of guidelines for medical tests or treatments.

Radiation therapy—Treatment using high-energy radiation from x-ray machines, cobalt, radium, or other sources.

Stage—The extent of the tumor. Tests are done to determine whether the tumor is localized to the organ or whether it has spread to the lymph nodes and/or other organs. Treatment is determined by the stage of the cancer.

Tumor—An abnormal growth of cells. Tumors may be benign (noncancerous) or malignant (cancerous).

the time of his/her diagnosis. Diagnosis of LFS depends upon the types of tumors family members have developed and the ages at which the tumors were diagnosed. A set of criteria for diagnosing LFS has been established.

A family may not meet the criteria for diagnosis of LFS but may have features that suggest LFS. Families such as these may be said to be “Li-Fraumeni-like” (LFL). Two sets of criteria have been developed for LFL, which, like the diagnostic criteria, are based upon the high incidence of tumors in these families and the early ages of diagnosis.

Caution needs to be used when evaluating a family history of early-onset breast cancer, that is, diagnosis in the 20s and 30s, since several other genes besides *TP53* are known to result in women’s having an increased risk of developing breast cancer at young ages. The clinical features of these other genes must be taken into account and evaluated while evaluating a family for LFS.

Genetic testing for *TP53* gene mutations is available and provides an additional method for making a diagnosis. It may be offered to an individual who has developed one of the tumors characteristic of LFS and who has a family history that meets the diagnostic criteria or strongly suggests LFS in order to confirm the diagnosis of LFS in the family. This is referred to as diagnostic testing. If a mutation is identified, the positive test result provides proof of the diagnosis. If no mutation is identified, this negative test result does not necessarily eliminate the diagnosis of LFS. Genetic testing may not identify a mutation for two reasons. First, laboratory techniques are not perfect, and not every mutation in the *TP53* gene has been or can be identified; about 70%–80% of mutations are identifiable. Second, it is possible that mutations in other genes, including *CHEK2*, contribute to a person's risk of LFS.

Genetic testing for LFS may be offered for a second reason. Genetic testing may be offered to an individual who has no personal history of cancer but whose family history meets the diagnostic criteria for LFS or is strongly suggestive of LFS. It is usually offered in order to determine this individual's risk of developing cancer and to help with decisions regarding medical screening. Genetic testing in this case is referred to as predictive or presymptomatic genetic testing. Predictive genetic testing should not be done unless a *TP53* genetic alteration has already been identified in an affected family member.

Genetic testing for diagnostic and predictive purposes is associated with significant risks and limitations, and uncertain benefits, and is best done with a geneticist (a doctor specializing in genetics) and/or genetic counselor knowledgeable about LFS and the implications of genetic testing. Predictive genetic testing for LFS does not provide a clear benefit for all family members at risk of inheriting a familial *TP53* gene alteration, since medical screening and prevention methods are not available for the tumors associated with LFS.

Prenatal diagnosis of LFS is available only if a *TP53* genetic alteration has already been identified in the family. Prenatal diagnosis of LFS is considered to be predictive genetic testing, and therefore the issues surrounding predictive genetic testing exist in this situation. An additional issue is how the test result will be used with regard to continuation of the pregnancy. Individuals considering prenatal diagnosis of LFS should confirm its availability prior to conception.

Treatment and management

There is no cure or method for preventing LFS. Treatment depends upon the tumor(s) that an individual develops. An individual does not require treatment until

QUESTIONS TO ASK YOUR DOCTOR

- What is the most serious health risk faced by a child diagnosed with Li-Fraumeni syndrome?
- Are there medications or medical procedures that can be used to cure my child's Li-Fraumeni syndrome or to reduce its severity?
- Are there books, pamphlets, brochures, or other material in which my child can eventually read about this condition?
- What is the best way to monitor the progress of my child's Li-Fraumeni syndrome over the years?

a tumor develops, and then the treatment will be specific to the type of tumor that has developed. An individual without symptoms should undergo regular medical checkups.

In general, tumors are treated by surgery, chemotherapy, and/or radiation therapy. Adrenocortical carcinomas and breast cancers, depending upon the stage of the tumor, use one or more of these treatments. Brain cancer is treated by surgery and/or radiation. In some cases, chemotherapy is also used. Leukemia is primarily treated by chemotherapy. In some cases, bone marrow transplantation is used. Osteosarcoma is treated by surgery. Rhabdomyosarcoma is treated by surgery, chemotherapy, and radiation therapy.

It is very important that an individual's physician be aware of the family history and the cancer risk. It has been suggested that children of a parent with LFS have a complete physical examination, urinalysis, complete blood count (CBC), and abdominal ultrasound examination each year. For adults at risk of having inherited a familial *TP53* gene alteration, it has been suggested that they undergo a complete physical examination with skin, nervous system, and rectal examinations once a year, and that women undergo a clinical breast examination every six months and mammography once a year. Women at risk should also begin having mammograms at an earlier age, usually around age 25.

According to the Li-Fraumeni Syndrome Association, however, it is difficult to develop a surveillance protocol that is applicable to all persons in a family with a history of LFS. This complexity is the result of the fact that people with LFS are at risk of several different types of hereditary tumors that develop at different points in the person's lifetime. An additional complication is psychological; as reported by a group of Yale cancer specialists

in 2015, some patients with LFS are made extremely anxious by intensive surveillance and may find repeated screening an emotional burden.

One recent protocol that has been recommended is a combination of blood tests, colonoscopy, mammography, ultrasound, breast MRI, brain MRI, and whole-body MRI. The Association points out that while this series of tests appeared to improve survival in the group of patients who received the screening, the tests are time-consuming and expensive, and the long-term benefits of this approach are unclear as of 2015. The Association recommends that patients with LFS discuss screening and surveillance with their doctors on an individual basis.

There is controversy concerning the use of mammography in women with LFS because of some suggestion that *TP53* gene alterations are sensitive to radiation. In general, an individual may decrease his/her chance of developing cancer by exercising on a regular basis, eating a healthy diet, limiting sun exposure, limiting alcohol intake, and not smoking. Lastly, an individual with or at risk of LFS should not delay seeing his or her physician if he or she notices a new or unusual symptom.

Prognosis

An individual who has LFS has a very high chance of developing a cancerous tumor by the time he/she is 60 years old. In contrast, individuals in the general population have about a 2% risk of developing cancer by the same age. The cancers associated with LFS each have a different prognosis, so an individual's prognosis is highly dependent upon the type of cancer he or she has developed. In some cases, prognosis is associated with how early the cancer has been found. For example, breast cancer found early has a better prognosis than breast cancer found later. In general, the cancers typically seen in LFS are curable if caught early. For this reason, regular medical screening is important. Prognosis may also be affected by the individual's overall health; consequently, being healthy and engaging in healthy behaviors may increase the chances of a good outcome.

Limb-girdle muscular dystrophy

Definition

Limb-girdle muscular dystrophy (LGMD) encompasses a diverse group of hereditary degenerative muscle disorders characterized by weakness and deterioration of the proximal skeletal muscles. Some doctors prefer to speak of these disorders in the plural—limb-girdle muscular dystrophies—because the various types differ widely in terms of frequency, severity, and associated genes.

Description

The term "limb-girdle muscular dystrophy" is used to describe a group of muscular dystrophies that cause a muscle deterioration that primarily affects the voluntary muscles around the limb girdle. The muscles of the limb girdle include those around the shoulders and hips. As the disease develops, the distal muscles of the limbs can become affected. Most individuals' muscles of the heart are not affected, but exceptions can occur. There are at least 24 different LGMDs (some researchers count as many as 30) that had been identified as of 2015, each having a different constellation of symptoms. Each of the muscular dystrophies results in an absent, deficient, or abnormal protein that is required for normal structure and function of the muscles. It can be difficult to differentiate

Symptoms of the limb-girdle muscular dystrophies

Type	Age of onset	Early symptoms	Late symptoms
*Sarcoglycanopathy (complete deficiency)	3–15 years (8.5 average)	Proximal weakness; Difficulty walk/run; Enlarged calf muscle	Contractures; Curvature in the spine; Wheelchair bound; Possible: Cardiac conduction defect; Dilated cardiomyopathy
**Sarcoglycanopathy (partial deficiency)	Adolescence/Young adulthood	Muscle cramps; Intolerance to exercise	
Calpainopathy	2–40 years (8–15 average)	Proximal weakness; Jutting backwards of shoulder blades (scapular winging); Decreased size of calf muscles; Contractures; Curvature in the spine	Wheelchair bound
Dysferlinopathy	17–23 years	Some patients have distal weakness and some have proximal weakness; Inability to tip-toe; Difficulties walk/run	
Telethoninopathy	Early teens		Wheelchair bound
LGMD2H	8–27 years		Wheelchair bound
LGMD2I	1.5–27 years		Wheelchair bound
LGMD1A	18–35 years	Proximal leg and arm weakness; Tight Achilles tendon; Problems with articulation of speech; Nasal sounding speech	Distal weakness
LGMD1B	4–38 years (50% onset childhood)	Proximal lower limb weakness	Contractures; Irregular heart beat; Sudden death due to cardiac problems (if untreated)
LGMD1D	<25 years	Proximal muscle weakness; Cardiac conduction defect; Dilated cardiomyopathy	All patients remain able to walk
LGMD1E	9–49 years (30 average)	Proximal lower and upper limb muscle weakness	Contractures; Difficulties swallowing
Caveolinopathy	Approx. 5 years	Mild to moderate proximal weakness; Muscle cramping; Enlargement of the calf muscles; Some have no symptoms	
Bethlem myopathy	<2 years	Floppy muscles in infancy; Proximal muscle weakness; Contractures	2/3 of patients are wheelchair bound by age 50

*Includes alpha, beta, gamma and delta sarcoglycanopathies that result in complete absence of a sarcoglycan protein

**Includes alpha, beta, gamma and delta sarcoglycanopathies that result in decreased amounts of a sarcoglycan protein

(Gale)

LGMD from other muscular dystrophies and muscle disorders that can also result in weakness in the limb girdle.

Genetic profile

Each type of limb-girdle muscular dystrophy is caused by changes in a different type of gene that produces a protein normally involved in the functioning of the skeletal muscles. Each gene is found at a specific location on a chromosome. Every person inherits two copies of a gene, one from their mother and one from their father. Each type of gene produces a specific type of protein. A change (mutation) in a gene can cause it to produce an abnormal protein, to produce an increased or decreased amount of normal protein, or to stop producing protein altogether. Abnormal or decreased amounts of skeletal muscle proteins can affect the development or functioning of the muscle cells, causing the symptoms of LGMD. Most forms of LGMD are autosomal recessive, although some rare forms are autosomal dominant. As of 2015, 16 forms of LGMD had been identified as autosomal recessive, and 8 forms as autosomal dominant.

The autosomal dominant forms are identified by the symbol LGMD1 followed by the letters A through H for the 8 subtypes. Similarly, the autosomal recessive forms are identified by the symbol LGMD2 followed by the letters A through Q.

An autosomal recessive form of LGMD is caused by a change in both genes of a pair. One of the changed genes is inherited from the egg cell of the mother, and one is inherited from the sperm cell of the father. Parents who have a child with an autosomal recessive form of LGMD are called carriers, since they each possess one changed *LGMD* gene and one unchanged *LGMD* gene. Carriers do not have any symptoms, as they have only one unchanged gene, which produces enough normal protein to prevent the symptoms of LGMD. Each child born to parents who are both carriers for the same type of LGMD has a 25% chance of having LGMD, a 50% chance of being a carrier, and a 25% chance of being neither a carrier nor affected with LGMD. Parents who are each a carrier for a different type of LGMD are not at increased risk for having children affected with LGMD.

The autosomal dominant forms of LGMD are caused by a change in only one gene of a pair. This changed gene is inherited from either the mother or the father. If the changed gene is inherited, each child born to a carrier of LGMD has a 50% chance of inheriting the condition. Sometimes the change occurs spontaneously when the egg and sperm come together to form the first cell of the baby. In this case, other relatives, such as siblings, are probably not at increased risk for inheriting LGMD. People with an autosomal dominant form of LGMD have a 50% chance of passing the condition on to their children. Some people who possess an autosomal dominant LGMD gene change do not have any symptoms.

Demographics

The incidence of the LGMDs is difficult to estimate, as the various subtypes can have a wide variety of symptoms. The rate of incidence of LGMD is 1 in 14,500–123,000 people and is found equally in men and women. LGMD is also difficult to differentiate from other muscular disorders. Some forms of LGMD are found more commonly in people of a certain ethnic background; for example, one rare form of autosomal recessive LGMD has been found only in people of Turkish ancestry and another only in people of Finnish ancestry.

Signs and symptoms

Each type of LGMD has a different range of symptoms. The symptoms can even vary among individuals with the same type of LGMD. The age of onset of symptoms can range from infancy to adulthood. In general, the

autosomal dominant subtypes of LGMD have a later onset in life than the autosomal recessive forms. The most common symptom of LGMD is muscle weakness and deterioration that involves the muscles around the hips and shoulders. The disorder progresses at a different rate in each person. Although individuals with an onset of the disorder in adulthood may have a slower progression and milder symptoms, the exact progression and extent of muscle deterioration cannot be predicted.

The first noticeable symptom of LGMD is often a waddling gait due to weakness of the hip and leg muscles. Difficulties in rising from a chair or toilet seat and difficulties in climbing stairs are common. Eventually, walking may become impossible and lead to the need of a wheelchair or scooter for locomotion. Enlargement or a decrease in size of the calf muscles can also be seen. Some individuals with LGMD also experience contractures and muscle cramps. The limited mobility associated with LGMD can result in muscle soreness and joint pain.

Lifting heavy objects, holding the arms outstretched, and reaching over the head can become impossible for people affected with LGMD because of weaknesses in the shoulder muscles. Some individuals with LGMD may eventually have difficulties swallowing and feeding themselves. Sometimes the back muscles can become weakened and result in scoliosis (curvature of the spine).

LGMD can occasionally result in a weakening of the heart muscles (cardiomyopathy) and/or the respiratory muscles. Some people may develop a conduction defect, an abnormality in the electrical system of the heart that regulates the heartbeat. A weakening of the muscles

Genetic causes of the limb-girdle muscular dystrophies

Type	Mode of inheritance	Gene involved	Chromosomal location
*Alpha-sarcoglycanopathy	Recessive	LGMD2D (SGCA)	17q12–q21.3
*Beta-sarcoglycanopathy	Recessive	LGMD2E (SGCB)	4q12
*Gamma-sarcoglycanopathy	Recessive	LGMD2C (SGCG)	13q12
*Delta-sarcoglycanopathy	Recessive	LGMD2F (SGCD)	5q33
Calpainopathy	Recessive	LGMD2A (CAPN3)	15q15.1–q21.1
Dysferlinopathy/Miyoshi distal myopathy	Recessive	LGMD2B (DYSF)	2q13.3–p13.1
Telethoninopathy	Recessive	LGMD2G (TCAP)	17q12
LGMD2H	Recessive	LGMD2H (TRIM32)	9q31–34.1
LGMD2I	Recessive	LGMD2I (FKRP)	19q13.3

	Dominant	COL6A2	21q22.3
	Dominant	COL6A3	2q37

* Each type of sarcoglycanopathy can result from a gene change that results in complete absence of sarcoglycan protein or decreased amounts of sarcoglycan protein.

(Gale)

Frequency of limb-girdle muscular dystrophy

Type	Frequency	Most common in:
Alpha-sarcoglycanopathy		None
Beta-sarcoglycanopathy	Majority with severe disease	Amish
Gamma-sarcoglycanopathy	10% of those with mild disease	North Africans; Gypsies
Delta-sarcoglycanopathy		Brazilian
Calpainopathy	Approximately 10%–30%	Amish; La Reunion Isle.; Basque (Spain); Turkish
Dysferlinopathy	Approximately 10%	Libyan Jews
Telethoninopathy	Rare	Italian
LGMD2H	Unknown	Unknown
LGMD2I	Unknown	Unknown
LGMD1A	Rare	Unknown
LGMD1B	Rare	Unknown
Caveolinopathy	Rare	Unknown
LGMD1D	Rare	Unknown
LGMD1E	Rare	Unknown
Bethlem myopathy	Rare	Unknown

(Gale)

necessary for respiration can cause breathing difficulties. LGMD does not, however, affect the brain and the ability to reason and think. Individuals with LGMD maintain normal bladder and bowel control and sexual functioning.

Diagnosis

No single test can diagnose LGMD. A diagnosis is based on clinical symptoms, physical examinations, and a variety of tests. The physician will first take a medical history to establish the type of symptoms experienced and the pattern of muscle weakness. Questions will usually be asked about the family history to see whether other relatives have similar symptoms.

It is necessary for the doctor to establish whether the weakness is due to problems with the muscles or due to a problem with the nerves that control the muscles. Sometimes this distinction can be accomplished through a physical examination. Electromyography testing is often performed to establish whether the weakness is in the nerves or the muscles. During electromyography, a needle electrode is inserted into the muscle and measurements are taken of the electrical activity of the muscle in response to stimulation by the nerves.

A blood test that measures the amount of creatine kinase is often performed. Creatine kinase is an enzyme that is produced by damaged muscles. High levels of creatine kinase suggest that the muscle is being destroyed, but high levels by themselves cannot indicate the cause of the damage. The most common causes of increased creatine kinase levels are muscular dystrophy and muscle inflammation.

A muscle biopsy will often be performed if LGMD is suspected. During the muscle biopsy, a small amount of

muscle is surgically removed. The muscle sample is examined to check for changes that are characteristic of muscular dystrophies. The amount and type of muscle proteins present in the sample can sometimes help to confirm a diagnosis of LGMD and can sometimes indicate the type of LGMD.

Ultimately, a diagnosis can be difficult to make, as there are many types of LGMD and a wide range of symptoms. It can also be difficult to differentiate LGMD from other muscular dystrophies that have similar symptoms, such as Becker and Duchenne muscular dystrophies. Anyone suspected of having LGMD should consider undergoing testing for other types of muscular dystrophies.

DNA testing for some forms of LGMD is now available through clinical and commercial laboratories. DNA testing is complicated by the many genes—at least 22 known as of 2015—and the types of gene mutations (changes) that can cause LGMD. To help with the cost and complexity of genetic testing for LGMD, a consortium of seven different muscular dystrophy foundations and healthcare systems is offering free genetic testing for these disorders (<http://lgmd-diagnosis.org/home>). Physicians who use the lgmd-diagnosis.org website can connect automatically to an online tool called the Automated LGMD Diagnostic Assistant (ALDA), developed by the Jain Foundation. ALDA is a subtyping tool that allows the physician to identify the most likely subtypes of LGMD affecting a given patient, thus saving the time and money that would be required to sequence all the genes that have been linked to LGMD. In October 2014, the American Academy of Neurology and the Practice Issues Review Panel of the American Association of

KEY TERMS

Amniocentesis—A procedure performed between 16 and 18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into the uterus to draw out a small sample of the amniotic fluid from around the fetus; either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Amniotic sac—Contains the fetus that is surrounded by amniotic fluid.

Autosomal dominant—A pattern of genetic inheritance in which only one abnormal gene is needed to display the trait or disease.

Autosomal recessive—A pattern of genetic inheritance in which two abnormal genes are needed to display the trait or disease.

Cardiac conduction defect—An abnormality of the electrical system of the heart that regulates the heartbeat.

Carrier—A person who possesses a gene for a trait without showing signs of the disorder; the person may pass the mutated gene on to offspring.

Chromosome—A microscopic thread-like structure found within each cell of the body that consists of a complex of proteins and DNA; humans have 46 chromosomes arranged into 23 pairs.

Contracture—A tightening of muscles that prevents normal movement of the associated limb or other body part.

Dilated cardiomyopathy—A diseased and weakened heart muscle that is unable to pump blood efficiently.

Distal muscles—Muscles that are farthest away from the center of the body.

DNA testing—Analysis of DNA (the genetic component of cells) in order to determine mutations in genes that may indicate a specific disorder.

Gene—A building block of inheritance that contains the instructions for the production of a particular protein and is made up of a molecular sequence found on a section of DNA; each gene is found on a precise location on a chromosome.

Limb girdles—The areas of the body around the shoulders and hips.

Prenatal testing—Testing for a disease, such as a genetic condition, in an unborn baby.

Protein—Important building blocks of the body, composed of amino acids, involved in the formation of body structures, and controlling the basic functions of the human body.

Proximal muscles—The muscles closest to the center of the body.

Scapular winging—The jutting-back of the shoulder blades that can be caused by muscle weakness.

Skeletal muscle—A muscle under voluntary control that attaches to bone and controls movement.

Neuromuscular and Electrodiagnostic Medicine issued updated guidelines about the importance of genetic testing in diagnosing the various subtypes of LGMD and guidance for physicians about which of the many genetic tests they should select.

DNA testing may be performed on a sample of blood cells or a sample of muscle cells. If an autosomal dominant gene mutation is detected in someone with LGMD, then both of the individual's parents can be tested to see whether the gene mutation was inherited. If the gene mutation was inherited, siblings can be tested to see whether they have inherited the mutated gene. If autosomal recessive gene mutations are detected, relatives, such as siblings, can be tested to see if they are carriers.

Prenatal testing for LGMD is available only if DNA testing has detected an autosomal dominant *LGMD* gene mutation in one parent or an autosomal recessive gene

mutation in both parents. Cells for prenatal testing are obtained through amniocentesis or chorionic villus sampling. These cells are analyzed for the *LGMD* gene mutation or mutations that were found in one or both parents.

Treatment and management

Physical therapy and exercises can often help keep the muscles and joints mobile and prevent contractures. Muscle and joint pain can be treated through exercise, warm baths, and pain medications. Surgical treatment of such complications as contractures or a curved spine may be necessary. Breathing exercises can sometimes help if breathing becomes difficult. If breathing independently becomes impossible, a portable mechanical ventilator can be used. A wheelchair or scooter can help when a person can no longer walk. Patients with autosomal dominant forms of LGMD should be carefully

QUESTIONS TO ASK YOUR DOCTOR

- How is limb-girdle muscular dystrophy different from other forms of muscular dystrophy?
- Please explain the process of gene therapy for this disorder and review the current state of research in this area.
- How can our family get in touch with organizations that provide information and support for families with some form of muscular dystrophy?
- How can you determine the prognosis for my child with limb-girdle muscular dystrophy?

monitored by a cardiologist for heart disorders. Medications are often prescribed for cardiomyopathies and heart conduction defects. A device such as a pacemaker that creates normal contractions of the heart muscle may be necessary for some people with heart muscle abnormalities.

Gene therapy may one day cure or improve LGMD. Gene therapy introduces unchanged copies of a *LGMD* gene into the muscle cells. The goal of therapy is for the normal *LGMD* gene to produce normal protein that will allow the muscle cells to function normally. Gene therapy clinical trials are still in their infancy. As of 2015, the two most notable trials of gene therapy for LGMD were one conducted in a laboratory in Paris and funded by the French Muscular Dystrophy Association and one conducted in the Center for Gene Therapy in the Nationwide Children's Hospital in Columbus, Ohio. It will take quite a few years, however, for gene therapy to become a viable way to treat LGMD.

Prognosis

The prognosis of LGMD varies tremendously. Most people with LGMD do not have severe symptoms, and most experience a normal life expectancy. Cardiac and respiratory difficulties may, however, shorten the patient's lifespan; patients who become wheelchair-bound in their early teens usually die of respiratory failure by their late teens.

Liquid biopsy

Definition

Liquid biopsy is a procedure in which a sample of non-solid human tissue is collected for analysis of DNA and other biomarkers present in body fluids. It is also called fluid biopsy or fluid phase biopsy. As of 2021, liquid biopsy most often involves blood samples, although cerebrospinal fluid has also been used to measure biomarkers of Alzheimer's disease. In addition, a recently introduced liquid biopsy test for prostate cancer uses urine samples.

Liquid biopsy. (Shutterstock/Abhinav Chaudhary)

Description

How the test is done

When blood is used for a liquid biopsy, the test is ordered by the patient's physician, most often a hematologist or oncologist. The blood is drawn from a vein in the patient's arm in the same way it is collected for other types of blood tests. In most cases, no special preparation is required, although the doctor may instruct the patient to temporarily discontinue certain prescription medications before the blood draw.

After the blood is collected, it is sent to a laboratory for analysis. There are two methods used for analyzing liquid biopsies as of 2021: polymerase chain reaction (PCR) and next-generation sequencing (NGS). In PCR, DNA fragments present in the blood are replicated (copied) thousands of times until there are enough copies for accurate identification and measurement. NGS is a platform that allows for the simultaneous sequencing of a number of regions of interest in the DNA fragments found in blood. PCR assays have the advantage of faster turnaround times and lower expense, while NGS is better able to detect previously unsuspected mutations in a patient's DNA. NGS has the disadvantages of higher

cost, longer turnaround times, and technical difficulty. In general, it can take anywhere from several days to more than a week for the results of a liquid biopsy to be reported to the patient's physician.

Biomarkers used in liquid biopsies

There are several different types of biomarkers that may be analyzed in blood taken for a liquid biopsy:

- **Cell-free DNA (cfDNA) and cell-free fetal DNA (cffDNA).** CfDNA was the first type of circulating DNA identified in human blood in 1948, but it attracted little interest at the time. It was not until 1977 that researchers noticed that the level of cfDNA is significantly higher in cancer patients than in healthy controls. Cell-free fetal DNA is released from the placenta into the bloodstream of a pregnant woman; it can be used after the tenth week of pregnancy to evaluate the presence of a chromosomal abnormality in the developing fetus.
- **Circulating tumor DNA (ctDNA).** This biomarker is released into the blood by tumor cells. It can be used to determine whether the tumor contains a genetic mutation indicating resistance to targeted therapy.

KEY TERMS

Analyte—The medical term for a substance or sample that is of interest in a laboratory test.

Assay—A laboratory test to identify and measure the amount of a specific substance.

Biomarker—A distinctive biological indicator of a process, event, disease, or other condition.

Companion diagnostic test—A test that provides information about the safety and efficacy of a corresponding medication. Some liquid biopsies are companion diagnostic tests.

Exosomes—Very small (between 30 and 150 nanometers in diameter) vesicles secreted by various types of cells that contain proteins, nucleic acids, or other biomolecules. Exosomes are of particular interest in liquid biopsy, because they can be found in blood, urine, and cerebrospinal fluid and thus may serve as biomarkers.

Hematology—The branch of medicine that deals with the diagnosis and treatment of diseases of the blood and bone marrow.

Next-generation sequencing (NGS)—A platform that allows for the simultaneous sequencing of a number of regions of interest in a patient's DNA.

Oncology—The branch of medicine concerned with the study, diagnosis, treatment, and prevention of cancer.

Platelets—Small, irregularly shaped particles in the blood that clump together to plug broken blood vessels during the process of blood clotting.

Polymerase chain reaction (PCR)—A method used to make millions to billions of complete or partial copies of a specific DNA sample in order to obtain a sufficient quantity to study in detail.

Precision medicine—An approach to health care that bases the prevention and treatment of disease on each individual's unique genetic makeup and lifestyle habits. It is sometimes called personalized medicine.

Targeted therapy—A type of drug or other substance that identifies and attacks specific types of cancer cells with less damage to normal cells. Most targeted therapy drugs are either monoclonal antibodies or small-molecule drugs.

Tumor-educated platelets (TEPs)—Platelets that have had their RNA profiles changed through association with cancerous tumors.

Vesicle—A membrane-bound structure within a cell in which enzymes and other materials are transported or stored.

- **Circulating tumor cells (CTCs).** These are cells shed into the bloodstream by the tumor. A circulating tumor cell count (CTC) is a type of liquid biopsy in which the number of circulating tumor cells in a given quantity of blood is measured and used to evaluate the patient's chances of successful treatment.
- **Exosomes (also called extracellular vesicles or EVs).** Exosomes, which are the single most common analyte in a liquid biopsy sample, contain a wide variety of different molecules, including nucleic acids, proteins, or lipids.
- **Tumor-educated platelets (TEPs).** Platelets are small, irregularly shaped particles in the blood that clump together to plug broken blood vessels during the process of blood clotting. Tumor-educated platelets, or TEPs, are platelets found in the blood of cancer patients that have distinct RNA profiles acquired from tumor cells.
- **MicroRNAs (miRNAs).** These are short single-stranded noncoding RNAs that control gene expression; they offer promise as biomarkers of the growth and progression of cancerous tumors. The last three biomarkers on this list are considered experimental in the development of liquid biopsy tests as of 2021.

Regulation and approval

The Food and Drug Administration (FDA) is the federal agency that oversees and regulates liquid biopsies as well as other technologies used in cancer treatment. Regulatory oversight of liquid biopsies is carried out in the Oncology Center of Excellence on the main FDA campus, which combines the review of oncology products from three different FDA centers: the Center for Drug Evaluation and Research; the Center for Biologics Evaluation and Research; and the Center for Devices and Radiological Health.

The FDA approved its first DNA-based liquid biopsy in June 2016, a diagnostic test called the cobas® EGFR Mutation Test v2. This is a PCR-based test that detects and sequences the epidermal growth factor receptor (*EGFR*) gene in patients with metastatic non-small-cell lung cancer. In the same year, the FDA approved the Epi proColon test, a blood test used to screen adults over 50 for colorectal cancer; it is also a PCR-based test.

In August 2020, the FDA approved two liquid biopsy tests based on NGS technology, which permits analysis of changes in multiple genes rather than just a

single gene. The first test, the Guardant360 CDx assay, identifies changes in 55 different genes to determine whether a patient with non-small-cell lung cancer (NSCLC) might benefit from a specific anticancer drug called osimertinib. The second test, the FoundationOne Liquid CDx, looks for mutations in 324 different genes. The FDA approved it as a companion diagnostic test for drugs used to treat advanced metastatic prostate cancer with mutations in the *BRCA1* and *BRCA2* genes, and NSCLC with *EGFR* mutations.

The FDA expanded the approved uses of the FoundationONE test in October and November 2020 to include other targeted drugs and genetic mutations related to advanced cancers of the breast and ovary, NSCLC, and metastatic prostate cancer.

Purpose

Liquid biopsy is increasingly important in personalized or precision medicine because of its growing role in identifying genetic mutations in malignant tumors. It is used for the following purposes as of mid-2021:

- To detect cancer at an early stage.
- To plan cancer treatment. Liquid biopsies that detect mutations in certain genes are useful in evaluating whether the patient will respond to targeted therapy.
- To evaluate how well therapy is progressing.
- To detect cancer spread or recurrence.
- To determine the presence of molecular changes in a cancerous tumor that may affect the tumor's response to treatment.
- To determine the patient's prognosis (likelihood of recovery). Circulating tumor cell counts are often used for this purpose, as prostate, breast, and colon cancers all have cutoff points above which the CTC count no longer has a favorable prognosis. The most commonly used CTC test since the early 2000s is CellSearch®, which uses specially coated beads to separate CTCs from other blood cells. CellSearch® was approved by the FDA for monitoring metastatic breast cancer; in 2007 for monitoring metastatic colorectal cancer; and in 2008 for monitoring prostate cancer.

Advantages and limitations

Liquid biopsy has the obvious advantage of being less invasive than a traditional tissue biopsy as well as being better tolerated by the patient; it also has a much lower risk of severe pain, infection, or uncontrolled bleeding. It can be repeated as often as needed to monitor a tumor or the progress of the patient's treatment. A liquid biopsy may detect genetic mutations in certain cancers—particularly lung cancer and melanoma—that do not appear in the specific samples removed for a

QUESTIONS TO ASK YOUR DOCTOR

- Have you ever ordered a liquid biopsy for one of your patients?
- If so, was it a circulating tumor cell test or a circulating tumor DNA test?
- Do you think that ongoing progress in sequencing technology and analysis of the various components in blood will make liquid biopsy a standard clinical tool?
- What do you consider the greatest obstacle to the increased use of liquid biopsy?

standard tissue biopsy. A liquid biopsy also can be useful when the patient's tumor is difficult to reach, as in certain types of head and neck or lung cancer.

As of 2021, however, a liquid biopsy is more often regarded as a complement to tissue a biopsy rather than as a replacement for it; it is not yet considered a standard clinical tool. A tissue biopsy is still usually needed to establish the initial diagnosis of cancer. Not all cancers shed DNA into the bloodstream, which means that a liquid biopsy is not helpful in monitoring those cancers that do not. Some types of liquid biopsy are very expensive or require specialized measurement techniques not readily available in most laboratories. Some biomarkers used in investigational liquid biopsies have not yet been standardized, meaning that they lack validated assays, are difficult or time-consuming to detect, or are not specific to a given cancer type.

Research

Three types of analytes in human blood are being studied for their potential in liquid biopsy tests: miRNAs, exosomes, and tumor-educated platelets (TEPs). There are 16 clinical trials of liquid biopsy tests based on exosomes registered with the NIH as of mid-2021, 14 trials of miRNA liquid biopsies, and two trials for TEP-based liquid biopsies. Researchers expect that these and other clinical trials will lead to newer types of liquid biopsy that can detect and monitor a wider range of cancers, provide more accurate prognoses for the patients, and improve the success rates of targeted therapies.

Lissencephaly

Definition

Lissencephaly, a term that means "smooth brain," is a rare congenital malformation of the brain that results in profound intellectual impairment and severe seizures.

Lissencephaly is caused by an arrest in development of the fetal brain during early pregnancy. The cerebral cortex, the top layer of the brain controlling higher thought processes, does not develop the normal sulci, the indentations or valleys in the cortex, and gyri, the ridges or convolutions seen on the surface of the cortex. Instead, the cortex in a person with lissencephaly is thickened and smooth with disorganized neurons that have not migrated to their proper places. The typical cortex has six layers of neurons, but brains with lissencephaly usually have only four.

Description

The condition was first reported in 1914 by pathologists Culp and Erhardt, who described a human brain with a smooth surface, lacking the normal gyri. They called it lissencephaly.

Lissencephaly is one of more than 20 conditions called neural migration disorders that occur because the developing neurons do not proceed correctly to their

Types of lissencephaly

Disorder	Inheritance	Gene location	Proportion of patients	Gene name	Protein product	Clinical test
MDS(Miller-Dieker syndrome)	AD	17p13.3	100%	LIS1	Platelet activating factor acetylhydrolase 45K	Yes
ILS1 (Isolated lissencephaly sequence 1)	AD	17p13.3	>40%	LIS1	Platelet activating factor acetylhydrolase 45K	Yes
X-linked lissencephaly and subcortical band heterotopia	X-linked	Xq22.3–q23	Unknown	XLIS	Unknown	No
Cobblestone lissencephaly (lissencephaly type 2)	AR	Unknown	Unknown	Unknown	Unknown	No

(Gale)

normal place in the brain's cortex during fetal development. In fact, the brain of a person with lissencephaly, with its smooth and immature cortex, resembles a typical human fetal brain at about 10 to 14 weeks of development.

Children with lissencephaly are almost always severely to profoundly intellectually impaired, and the vast majority develop seizures that are difficult to treat. Life expectancy is reduced, and survivors need constant care.

Lissencephaly can occur as an isolated birth defect or can be one of many abnormalities occurring together in a specific inherited syndrome. There are at least 10 inherited syndromes that include lissencephaly and many more that include variants of this brain malformation. Lissencephaly can also occur by itself without other characteristics.

Some cases of lissencephaly are caused by new changes in the genetic material of that particular baby—these cases are caused by sporadic, or random, gene mutations (also called *de novo*). This means that the genetic change is not present in the parents or anyone else in the family. Some cases of lissencephaly are caused by rearrangements of chromosome material that can be inherited from a healthy parent. Other types of lissencephaly are inherited in an autosomal recessive pattern. This means that a couple who has a child with an autosomal recessive lissencephaly syndrome has a 25% chance in any future pregnancy to have another affected child. There are also types of lissencephaly caused by changes in a gene or genes on the X chromosome. X-linked lissencephaly affects mainly males, who have only one X chromosome. Females who carry an X-linked gene change on one of their two X chromosomes often have mild brain changes.

Other known causes of lissencephaly include viral infections of the fetus or insufficient blood supply to the brain during the first trimester of pregnancy.

The medical community has categorized lissencephaly in several ways. There are over 20 different types

of lissencephaly and it is a component of many different syndromes. The simplest way to distinguish between types of lissencephaly is based on the phenotype or physical features. Using this approach, lissencephaly may be divided into three main types:

Classical or type 1 lissencephaly

In this type of lissencephaly the surface of the brain is completely smooth except for a few shallow valleys (sulci). The cortex is thicker than normal and there are clumps of neurons found in areas outside the cortex (heterotopia). The corpus callosum, the band of tissue between the hemispheres of the brain, is often small and is sometimes absent. The posterior ventricles, the fluid-filled spaces in the center of the brain, are often larger than normal.

Type 1 lissencephaly can be seen in a number of genetic syndromes and can also occur by itself in a condition called isolated lissencephaly sequence (ILS). The vast majority of cases of ILS is a result of mutations or deletions (missing sections) in one of two different genes involved in brain development.

An example of a genetic syndrome involving type 1 lissencephaly is Miller-Dieker syndrome (MDS). This disorder is caused by a deletion of part of the short arm of chromosome 17 (17p13) that includes the *LIS1* gene. In addition to lissencephaly, children with MDS have distinctive facial features including a high forehead, short upturned nose, and thin lips. They also have narrowing at the temples and a small jaw, although these traits can also be seen in ILS and other lissencephaly syndromes. Children with MDS occasionally have other birth abnormalities of the heart, kidneys, or palate. Calcium deposits in the midline of the brain are common in MDS, but not in ILS or other syndromes.

Cobblestone dysplasia or type 2 lissencephaly

Type 2 lissencephaly is also called cobblestone dysplasia because of the pebbled appearance to the surface of the cerebral cortex. Brains with cobblestone

dysplasia often show abnormalities of the white matter, enlarged ventricles, underdeveloped brain stem and cerebellum, and absence of the corpus callosum.

There are four known syndromes that include cobblestone dysplasia: cobblestone lissencephaly without other birth defects (CLO), Fukuyama congenital muscular dystrophy (FCMD), muscle-eye-brain disease (MEB), and Walker-Warburg syndrome (WWS). These disorders are quite rare, and all are inherited in an autosomal recessive pattern. Diagnosis depends on MRI studies and clinical evaluations. There are no specific genetic tests available for clinical use for these conditions.

Other types of lissencephaly

There are other rare syndromes involving lissencephaly and variants of lissencephaly; these syndromes and variants may involve the completely smooth brain seen in classic lissencephaly, the pebbled appearance seen in cobblestone dysplasia, or may involve varying degrees of abnormalities of the cerebral cortex. Examples of other types of lissencephaly include X-linked lissencephaly and subcortical band heterotopia. X-linked lissencephaly is characterized by varying degrees of abnormal folds and grooves of the cerebral cortex. The smoother the brain surface, the more severe the symptoms seen in that individual. Other symptoms include abnormal genitalia that can include an unusually small penis (micropenis), undescended testes (cryptorchidism), or external genitalia that do not look clearly male or clearly female (ambiguous genitalia).

Genetic profile

Lissencephaly has been associated with mutations on several genes. The gene causing the majority of cases of ILS is called the *PAFAH1B1* (or *LIS1*) and is located on the short arm of chromosome 17. Between 40% and 64% of persons with ILS have a deletion of a portion of the *PAFAH1B1* gene, and about 24% have a mutation that disrupts the normal function of the gene. Most deletions and mutations in the *PAFAH1B1* gene are sporadic and are not present in other family members. Another 12% of persons with ILS have a mutation in a gene called *DCX* (or *XLIS*), located on the long arm of the X chromosome. Mutations in *XLIS* cause X-linked lissencephaly in males and may or may not cause symptoms in the mothers who carry the mutation.

Classical or type 1 lissencephaly is caused by mutations in the *PAFAH1B1* (*LIS1*), *DCX*, and *TUBA1A* genes. These genes are responsible for the production of the double-cortin, acetyl hydrolase 1B (*PAFAH1B*), and alpha-tubulin (α -tubulin) proteins. These proteins are important in the development of the fetal brain. When

KEY TERMS

Agyria—The absence of gyri, or convolutions, in the cerebral cortex.

Cerebellum—A portion of the brain consisting of two cerebellar hemispheres connected by a narrow vermis. The cerebellum is involved in control of skeletal muscles and plays an important role in the coordination of voluntary muscle movement. It interrelates with other areas of the brain to facilitate a variety of movements, including maintaining proper posture and balance, walking, running, and fine motor skills such as writing, dressing, and eating.

Cerebral cortex—The outer surface of the cerebrum made up of gray matter and involved in higher thought processes.

Congenital malformation—A birth defect or physical abnormality present at birth.

Corpus callosum—A thick bundle of nerve fibers deep in the center of the forebrain that provides communications between the right and left cerebral hemispheres.

Heterotopia—Small nodules of gray matter that are present outside the cortex.

Lissencephaly—A condition in which the brain has a smooth appearance because the normal convolutions (gyri) failed to develop.

Magnetic resonance imaging (MRI)—A technique that employs magnetic fields and radio waves to create detailed images of internal body structures and organs, including the brain.

Microcephaly—An abnormally small head.

Pachygyria—The presence of a few broad gyri (folds) and shallow sulci (grooves) in the cerebral cortex.

Prenatal diagnosis—The determination of whether a fetus possesses a disease or disorder while it is still in the womb.

Subcortical band heterotopia—A mild form of lissencephaly type 1 in which abnormal bands of gray and white matter are present beneath the cortex near the ventricles.

Ventricle—The fluid-filled spaces in the center of the brain that hold cerebral spinal fluid.

these proteins do not form correctly or in correct numbers, it affects formation of neurons and neural migration, the process by which neuron move to the appropriate location within the brain. These abnormalities lead to lissencephaly.

Cobblestone dysplasia or type 2 lissencephaly is caused by mutations in the *FKTN*, *FKRP*, *LARGE*, *RELIN*, *POMGnT1*, *POMT1*, *POMT2*, and *TUBA1A* genes. These genes are responsible for the production of the FKRP, fukutin, ISPD, LARGE, POMT complex, reelin, and alpha-tubulin (α -tubulin) proteins. These proteins, like those associated with type 1 lissencephaly, are important in the development of the fetal brain and in neural migration and abnormalities in them lead to type 2 lissencephaly.

X-linked lissencephaly and subcortical band heterotopia are caused by mutations in genes located on the X chromosome. X-linked lissencephaly is inherited in an X-linked pattern meaning that the mutated gene that causes the disorder is located on the X chromosome, one of the two sex chromosomes in each cell. Males have only one X chromosome, and therefore one altered copy of the gene in each cell is sufficient to cause the condition. In females, who have two copies of the X chromosome, one altered copy of the gene in each cell may lead to less severe brain malformations or may cause no symptoms at all. In X-linked inheritance, fathers cannot pass X-linked traits to their sons because sons receive their only X chromosome from their mothers. These mutations affect formation of the *ARX* gene and the ARX protein and cause abnormal neural migration in the developing fetus that lead to lissencephaly.

Subcortical band heterotopia is a rare form of lissencephaly that is inherited in an X-linked dominant pattern, meaning that only one copy of the gene must be present for an individual to have the condition. It affects females more than males. It is also caused by mutations in the *PAFAH1B1* (*LIS1*) gene located on chromosome 17. As in the other forms of lissencephaly, mutations in this gene lead to neural migration delays and cause the abnormal brain formation of lissencephaly.

Demographics

Lissencephaly affects fewer than 1 in 100,000 individuals and occurs in all parts of the world. The sporadic and autosomal recessive types of lissencephaly occur equally in males and females. X-linked syndromes that include lissencephaly occur mainly in boys, although carrier mothers sometimes have milder signs.

Signs and symptoms

Many babies with lissencephaly appear normal at birth, although some have immediate respiratory problems. After the first few months at home, parents typically notice feeding problems, inability to visually track objects, and lessened activity in their child. Breath-holding spells (apnea) and muscle weakness are also

common. Seizures frequently begin within the first year of life, are usually severe, and are difficult to treat with medication. Muscle weakness changes to spasticity (a condition of excessive muscle tension) over time. Repeated pneumonias from swallowing food down the airway and into the lungs are common.

Head size is usually within normal limits at birth; however, as the baby's body grows, head growth lags and a small head (microcephaly) results. Babies with isolated lissencephaly often have hollowing at the temples and small jaws, both thought to be a result of the abnormal brain shape. Genetic syndromes involving lissencephaly will include other symptoms and signs.

Diagnosis

The diagnosis of lissencephaly is initially based on tests using magnetic resonance imaging (MRI) and computed tomography (CT) scans. MRI findings in type 1 lissencephaly include a lack of, or very shallow, convolutions on the surface of an unusually thick cerebral cortex. Enlargement of the ventricles is sometimes present.

On average, persons with Miller-Dieker syndrome have more severe MRI findings than persons with ILS. It is sometimes possible to distinguish between chromosome 17-related lissencephaly (ILS and MDS) and X-linked ILS based on MRI findings. The smooth brain appearance is more striking in the back portion of the brain in persons with chromosome 17 *LIS1* deletions and mutations. In contrast, it is more conspicuous in the front part of the brain in persons with *XLIS* mutations. In addition, underdevelopment of part of the cerebellum is more commonly seen in persons with *XLIS* mutations.

Individuals with subcortical band heterotopia (SBH), a milder form of lissencephaly often seen in female carriers of *XLIS*, often have minor changes in the gyri, shallow sulci, and ribbons of white and gray matter beneath the cortex that show up on MRIs.

MRI findings in type 2 lissencephaly can include a cobblestone appearance of the cortex, enlarged ventricles, abnormalities of the white matter, and changes in the cerebellum, corpus callosum, and brain stem.

A CT scan can be done to look for calcium deposits in the midline of the brain. Calcium deposits are common in MDS but not found in other lissencephaly syndromes.

In addition to MRI and CT testing, a careful clinical evaluation and examination by a medical geneticist is necessary to confirm the diagnosis and evaluate the child for the presence of a syndrome. It is essential for a child to have a precise diagnosis in order for genetic counselors to be able to give the family complete and accurate information about the inheritance pattern and chances for the condition to recur in future children.

To confirm the diagnosis of MDS or ILS, chromosome testing and other specialized genetic tests are often helpful. A test called fluorescent in situ hybridization (FISH) is used to detect *LIS1* gene deletions. High-resolution chromosome testing can often determine whether a deletion is sporadic or due to an inherited chromosome rearrangement. If necessary, mutation analysis, looking for specific errors in the sequence of the *LIS1* or *XLIS* gene, can be performed.

Parents of a child with ILS who have a confirmed deletion or mutation in *LIS1*, and who have normal genetic studies themselves, have a less than 1% chance of having another child with ILS. Similarly, MDS with a confirmed sporadic deletion in *LIS1* has a low chance of recurring. MDS caused by a chromosome rearrangement carries a higher chance of happening again. Actual risks depend on the specific rearrangement.

XLIS mutations are often inherited from a carrier mother. If a woman has genetic testing and is confirmed to have an *XLIS* mutation, she will have a 25% chance with each pregnancy to have an affected male and a 25% chance to have a carrier female who may have SBH.

If a detectable mutation, deletion, or chromosome rearrangement has been confirmed in the affected family member, prenatal diagnosis is available during future pregnancies. Ultrasound of the fetal anatomy during pregnancy cannot diagnose lissencephaly. However, ultrasound performed by a specialist at 18 to 22 weeks of pregnancy can sometimes detect other birth abnormalities that occur in some of the syndromes involving lissencephaly.

Treatment and management

There is no treatment or cure for lissencephaly. Seizures occur in almost all children with lissencephaly and are often difficult to control, even with the strongest anti-seizure medications. A severe type of seizure called infantile spasms can occur and may need to be treated with injections of adrenocorticotrophic hormone (ACTH), although this treatment is not always effective.

Feeding difficulties can include choking, gagging, or regurgitating food or liquid. Aspiration—swallowing food down the trachea and into the lungs—is a serious problem that can lead to pneumonia. Liquids and thick foods can be thinned to make swallowing easier. There are medications available to help with reflux. Children who continue to have serious problems may need a permanent feeding tube placed into the stomach to ensure adequate nutrition.

Physical and occupational therapy can help prevent or reduce tightening of the joints and help to normalize

muscle tone. However, the improvements are often limited and temporary.

Prognosis

Persons with classical lissencephaly usually need life-long care for all basic needs. Many babies do not live past infancy, but the average age of survival depends on the particular syndrome involved, the type of lissencephaly, and the severity of the brain abnormalities in a given child. Babies with MDS usually die by two years of age, but the majority of persons with ILS live into childhood, although often not into adulthood. Many babies with cobblestone dysplasia die in infancy; however, some affected people have lived into their 20s. In contrast, persons with SBH have very variable signs and symptoms, may be asymptomatic, mildly affected, or severely intellectually disabled, and may have near-normal or normal lifespans.

Long QT syndrome

Definition

Long QT syndrome (LQTS) is the overarching term used to describe a family of genetic or acquired disorders that are characterized by irregular heartbeats caused by problems in the heart's electrical activity (cardiac arrhythmias). The cardiac arrhythmias of long QT syndrome can lead to fainting (syncope), cardiac arrest, and sudden death. The syndrome is characterized by a longer-than-normal QT interval on an electrocardiogram.

Description

LQTS is one of the sudden arrhythmia death syndromes (SADS). It is a major cause of sudden, unexplained death in children and young adults, resulting in as many as 3,000–4,000 deaths per year in the United States. Its characteristic symptoms include seizures or fainting, often in response to stress, and long QT intervals found on an electrocardiogram.

LQTS was first described by C. Romano and co-workers in 1963 and by O. C. Ward in 1964 as a syndrome that was almost identical to Jervell and Lange-Nielsen syndrome but without congenital deafness. Therefore, the condition is known as Romano-Ward syndrome or Ward-Romano syndrome. Because other genetic disorders are now known to be associated with long QT syndrome, Romano-Ward syndrome is identified by the symbol LQT1 or as long QT syndrome type 1.

LQTS involves irregularities in the recharging of the heart's electrical system that occurs after each heartbeat or contraction. The QT interval is the period of relaxation or recovery that is required for the repolarization, or recharging, of the electrical system following each heart contraction. Depolarization, or electrical activity that causes heart contraction, and repolarization are orchestrated by the flow of potassium, sodium, and calcium through the heart cell's ion channels. As sodium channels in the heart open, positively charged sodium ions flow into the cells, making the inner surfaces of the cell membranes more positive than the outside and creating the action potential or electrical charge. During depolarization, the sodium channels shut, and after a delay, potassium channels open and allow positively charged potassium ions to move out of the cells, returning the cell membranes to their resting state in preparation for the next heart contraction.

Individuals with LQTS have an unusually long period of relaxation or recovery called the QT interval after each heart contraction. If the electrical impulse for the next contraction arrives before the end of the QT

recovery period, a specific arrhythmia arises in the ventricles (lower chambers) of the heart. This arrhythmia is called polymorphous ventricular tachycardia, meaning fast heart (above 100 beats per second), or *torsades de pointes*, which means turning or twisting of the points. A normal heartbeat begins in the right atrium of the heart and progresses down to the ventricles. In ventricular tachycardia or *torsades de pointes*, the heartbeat may originate in the ventricle. Usually this very fast and abnormal heartbeat reverts to normal. If it does not, it leads to ventricular fibrillation (VF), in which the heart beats too quickly, irregularly, and ineffectively. This arrhythmia can result in cardiac arrest and death. Variations in the QT interval from one heart cell to another also can cause arrhythmias and ventricular fibrillation in LQTS.

LQTS usually results from changes (mutations) in one of 13 or more genes. These genes encode proteins that form the ion channels in the heart. Depending on the other functions of the gene that is mutated, features beyond irregular heartbeats may occur in individuals affected by the different forms of LQTS. Although some mutations causing LQTS can arise spontaneously in an individual, they are most often passed on from parent to offspring. Thus LQTS usually runs in families.

Acquired LQTS is caused by factors other than genetic inheritance or mutation. Many different medications, including heart medicines, antibiotics, digestive medicines, psychiatric drugs, and antihistamines, as well as certain poisons, can result in LQTS. Some of these drugs block potassium ion channels in the heart. Diuretic medications can cause LQTS by lowering levels of potassium, magnesium, and calcium in the blood. Mineral

A comparison of the "QT" interval found in a normal patient versus one diagnosed with long QT syndrome obtained from an electrocardiogram. The typical QT interval is 400–440 milliseconds, but for patients with long QT syndrome the interval exceeds 460 milliseconds. This lengthened interval is obvious in the comparison above. (Gale)

imbalances, resulting from chronic vomiting, diarrhea, anorexia, malnutrition, or starvation, can also result in LQTS. Such additional medical issues as strokes, some neurological problems, or alcoholism also can cause LQTS. However, since only certain individuals develop LQTS under these circumstances, multiple genetic factors play a role in the acquired disorder.

Genetic profile

Although all of the genes that are known to be involved in LQTS encode proteins that form sections or subunits of ion channels through cellular membranes, the type of LQTS depends on the specific gene defect. Although new genetic mutations that cause LQTS are still being discovered, the majority of inherited LQTS cases result from mutations in *KVLQT1* or *KCNQ1*, causing LQT1, or mutations in *hERG* or *KCNH2*, causing LQT2.

Most types of LQTS are autosomal dominant genetic disorders: the genes that cause LQTS are carried on one of the 22 pairs of numbered autosomal chromosomes, rather than on the X or Y sex chromosomes. Furthermore, in autosomal dominant conditions, only one copy of the mutant, or nonworking, gene is necessary for the development of LQTS. An individual who inherits a normal gene copy from one parent and an abnormal gene copy from the other parent is likely to have LQTS. The children of an individual with one normal gene copy and one mutated copy have a 50% chance of inheriting LQTS.

Some types of LQTS are inherited in an autosomal recessive pattern. In an autosomal recessive pattern, two copies of the mutant, or nonworking, gene are needed to develop the symptoms of LQTS. In these cases, both parents each carry one copy of a mutant gene. Individuals with only one copy of a nonworking gene for a recessive condition are known as carriers and have no problems related to the condition. In fact, each person carries between 5 and 10 nonworking genes for harmful, recessive conditions. However, when two people with the same nonworking recessive gene have children together, there is a 25% chance with each pregnancy for the child to inherit two nonworking copies, one from each parent. That child then has no working copies of the gene and has the signs and symptoms associated with a recessive condition.

Long QT syndrome 1 and long QT syndrome 5

Long QT syndrome 1 (LQT1) is the most common form of LQTS, accounting for about 45% of cases. It is caused by any of a number of gene mutations in the *KVLQT1* (*KvLQT1*) gene located on the short arm of chromosome 11 (11p15.5). *KVLQT1* is also known as *KCNQ1*. The *KVLQT1* gene codes a critical part of a

voltage-gated potassium ion channel that helps the heartbeat. Even if the *KVLQT1* creates an abnormal potassium ion channel part, it can still join with the other parts of the channel. A potassium ion channel that is constructed with an abnormal part or subunit does not work as well as a channel formed of all normal parts. Most mutations in *KVLQT1* causing LQT1 are passed down in an autosomal dominant pattern through the family; however, some mutations in this gene may be passed down in an autosomal recessive pattern. In these cases, LQTS is present only in individuals with two abnormal *KVLQT1* genes, one inherited from each parent. The pattern of inheritance depends on which type of LQTS-causing mutation is present in the family because some mutations cause a potassium ion channel part that works better than other mutations. Mutation analysis of the *KVLQT1* gene and/or a detailed medical family history can determine the inheritance pattern of LQT1 in a specific family.

The *KCNE1* (*MinK* or *IsK*) gene on chromosome 21 codes for another critical part of the voltage-gated potassium ion channel that combines with the part encoded by *KVLQT1*. Together, they form the ion channel that is responsible for the heart's potassium current. The channel encoded in *KCNE1* and *KVLQT1* is a slow ion channel that starts working when the heart is in depolarization. Depolarization of the heart causes the channel to open and potassium ions to move freely out of the cells during repolarization. Mutations in *KCNE1* also can cause a defective potassium channel protein, resulting in a LQT1 form of LQTS; however, LQTS resulting from mutations in *KCNE1* may also be referred to as long QT syndrome 5 (LQT5). Mutations in potassium channel genes reduce the number of functional potassium channels in the heart and lengthen the QT interval by delaying depolarization.

Jervell and Lange-Nielsen syndrome

Jervell and Lange-Nielsen syndrome (JLNS) is a specific autosomal recessive form of LQTS. In JLNS, an individual has inherited two copies of an abnormal *KVLQT1* or *KCNE1* gene: one inherited from the mother and the other from the father. The syndrome is characterized by congenital deafness, as well as a prolonged QT interval.

Long QT syndrome 2 and long QT syndrome 6

Long QT syndrome 2 (LQT2) is the second most common form of LQTS, accounting for about 42% of cases. Mutations in the *hERG* gene (so named because it is the human equivalent of a fruit fly gene called ether-à-go-go) can result in LQT2. *hERG*, located on chromosome 7 (7q35-q36), encodes a protein part of another potassium

ion channel found in the heart. Mutations in *hERG* result in loss of the potassium current called IKr.

Long QT syndrome 6 (LQT6) is caused by mutations in the *KCNE2* gene. The *KCNE2* or *MiRP1* (for *MinK*-related) gene is located on chromosome 21 (21q22.1). The gene encodes a protein part that combines with the protein encoded by *hERG* to form a potassium ion channel used in the heart. Mutations in potassium channel genes reduce the number of functional potassium channels in the heart and lengthen the QT interval by delaying depolarization.

Long QT syndrome 3

Mutations in the *SCN5A* gene can result in a less common form of LQTS known as long QT syndrome 3 (LQT3). About 7% of cases of long QT syndrome are diagnosed as LQT3. *SCN5A*, on the short arm of chromosome 3 (3p21), encodes a part of a cardiac sodium ion channel. Some mutations in this gene prevent the channel from being turned off or inactivated. Thus, although the channel opens normally and sodium ions flow into the cells with each contraction, the channel does not close properly. Sodium ions continue to leak into the cells, which prolongs the action potential.

Brugada syndrome

Brugada syndrome is caused by a mutation in *SCN5A*, located on the short arm of chromosome 3 (3p21). The type of mutation that causes Brugada decreases the flow of sodium ions into the cells and shortens the time of action potential. The symptoms of Brugada syndrome, which include ventricular arrhythmia, cardiac arrest, and sudden death, are caused by the shortened action potential.

Long QT syndrome 4

Long QT syndrome 4 (LQT4) is a very rare condition; it is most often referred to as sick sinus syndrome with bradycardia. LQT4 is associated with mutation in the ankyrin-B gene called *ANK2*, which is located on the long arm of chromosome 4 (4q25-q27). *ANK2* plays a vital role in the organization of a sodium pump that exchanges sodium and calcium in and out of the heart. A mutation in the *ANK2* gene reduces the ability to get necessary proteins and calcium to the heart cells. Individuals with LQT4 have the typical cardiac dysfunction seen in LQTS. However, a long QT interval is not always seen in individuals with LQT4, so it is considered a condition distinct from classical long QT syndromes.

Long QT syndrome 7

Long QT syndrome 7 (LQT7) is also known as Andersen cardiodysrhythmic periodic paralysis, Andersen

syndrome, periodic paralysis, potassium-sensitive cardiodysrhythmic type, and Andersen-Tawil syndrome. LQT7 is associated with mutations in the *KCNJ2* gene located on the long arm of chromosome 17 (17q23.1-q24.2). Mutations in *KCNJ2* decrease the ability of a potassium channel in the heart to react to a specific important protein, called phosphatidylinositol 4,5-bisphosphate (PIP2), and move potassium in and out of the body's muscles. The movement of potassium in and out of the body's muscles allows movement of the arms, legs, and other muscles.

Long QT syndrome 8 with syndactyly

Long QT syndrome 8 with syndactyly is also known as LQT8 or Timothy syndrome (TS). Long QT syndrome 8 with syndactyly is caused by new mutations in the *CACNA1C* gene located on the short arm of chromosome 12 (12p13.3). Mutations in *CACNA1C* keep calcium ion channels open and pull in calcium ions. By constantly pulling in calcium ions, repolarization is delayed and the chance of an irregular heartbeat (arrhythmia) is increased.

Long QT syndrome 9

Long QT syndrome 9, or LQT9, was identified in 2006 and traced to a mutation in the *CAV3* gene on the short arm of chromosome 3 at 3p25. This gene codes for caveolin-3, a protein that is the main component of caveolae, small pouches in the membranes of muscle cells. It is thought that mutations in the *CAV3* gene disrupt ion transport through sodium channels in the caveolae in heart muscle, thus leading to the abnormal heart rhythm found in long QT syndrome. LQT9 has been particularly implicated in SIDS deaths.

Other forms of LQTS

A small number of individuals with LQTS have mutations in more than one of the known genes and may have symptoms of multiple LQTS types. Other families with inherited LQTS lack mutations in any of these known genes, suggesting the existence of other genes that can cause LQTS. Furthermore, individuals with identical LQTS genes may differ significantly in the severity of their symptoms, again suggesting the existence of other genes that can cause or modify LQTS. Between 2000 and 2005, several large studies characterized the presence of gene variants or alleles in genes, including *KCNA5*, *KCNQ1*, *KCNH2*, *KCNE1*, and *KCNE2*, that help control the length of the QT interval.

Between 2005 and 2015, mutations in such other genes as *CAV3*, *SCN4B*, *AKAP9*, *SNTA1*, and *KCNJ5* were identified as contributing to various subtypes of long QT syndrome. Some of these mutations were identified in only one patient or one family. In 2007, mutations

in the *SCN4B* gene on the long arm of chromosome 11 (11q23.3) were identified as the cause of LQT10, a rare form of LQTS found in only three people in one family as of 2015. LQT11 was also identified in 2007 and traced to a mutation in the *AKAP9* gene on the long arm of chromosome 7 at 7q21.2. This mutation has been identified in only two people—sisters in the same Caucasian family. LQT12, caused by a mutation in the *SNTA1* gene on chromosome 20 at 20q11.21, had been identified in only one patient as of 2015. The *SNTA1* mutation interacts with the *SCN5A* gene to increase the flow of sodium ions. LQT13 was identified in 2010 in a Chinese family and was traced to a mutation in the *KCNJ5* gene on the long arm of chromosome 11 at 11q23.3.

Demographics

Large-scale studies of LQTS, such as the International Registry for LQTS established in 1979, have revealed that the disorder is much more prevalent than was originally thought. Inherited LQTS is estimated to occur in 1 out of every 5,000–10,000 individuals and occurs in all racial and ethnic groups worldwide. Some researchers think that LQTS is underdiagnosed. LQTS may result in fetal death. It (especially LQT9) accounts for some cases of SIDS and has been implicated in many instances of sudden death and unexplained drowning among individuals who were previously without symptoms.

As an autosomal non-sex-linked genetic disorder, LQTS should affect males and females in equal numbers. However, it appears to be more prevalent among women. Nearly 70% of the time, a female is the first member of a family recognized as having LQTS. Females are two to three times more likely than males to exhibit symptoms of LQTS. In general, however, males manifest symptoms of LQTS at an earlier age than females. At puberty, the QT interval shortens in males, whereas in females it stays the same or shortens only slightly. Therefore, unaffected women have slightly longer QT intervals than unaffected men. Men with LQT1 or LQT2 have shorter QT intervals than either women or children with these two forms of the disorder. Women also are more likely than men to develop drug-induced or acquired LQTS. These gender-related differences may be due to the effects of the female hormone estrogen on the regulation of cardiac ion channels, particularly potassium channels.

Signs and symptoms

Tragically for many individuals with LQTS, sudden death by cardiac arrest is the first symptom. For this reason, LQTS sometimes is referred to as a “silent” killer. Approximately one-third of deaths from LQTS are not preceded by any symptoms of the disease. At least one-

third of the individuals carrying a gene variant that causes LQTS do not exhibit any symptoms. SIDS claims the lives of 1 or 2 out of every 1,000 infants. In 1998, the results of the Multicenter Italian Study of Neonatal Electrocardiography and a SIDS study found that a large number of SIDS victims had prolonged QT intervals.

Common symptoms of LQTS include dizziness, sudden loss of consciousness or fainting spells (syncope), or convulsive seizures. These occur because the heart is unable to pump sufficient blood to the brain. Following a loss of consciousness or syncope, the *torsades de pointes* rhythm (fast heartbeat of the lower heart chambers) usually reverts spontaneously to a normal rhythm within one minute or less, and the individual regains consciousness. These symptoms may first appear during infancy or early childhood, although sometimes no symptoms are evident until adulthood. Some individuals may experience syncopal episodes from childhood on, whereas others may experience one or two episodes as children, with no recurrence throughout adulthood. On average, males with LQTS first exhibit symptoms at about age eight and females at about age 14. These symptoms usually occur upon awakening, during strenuous physical activity, during a rapid change in posture, or during moments of excitement or stress.

Affected newborn infants and children under the age of three may exhibit slower than normal resting heart rates. Individuals with LQTS may experience irregular heartbeats accompanied by chest pain.

Symptoms of LQTS can vary depending on the specific gene mutation. Certain mutations in the *KVLQT1* gene that cause LQT1 may result in arrhythmias when an individual is under stress. Exercise is a major trigger for cardiac events in LQT1. Swimming can trigger syncopic episodes and appears to be a gene-specific trigger in individuals with *KVLQT1* mutations. Sudden loud noises, such as telephones or alarm clocks, are more likely to trigger arrhythmias and syncopic episodes in individuals with LQT2. Cardiac events, including syncope, aborted cardiac arrest, and sudden death, are more common among individuals with LQT1 or LQT2 than among those with LQT3. However, cardiac events are more likely to be lethal in individuals with LQT3. Certain variants of the *SCN5A* gene that cause LQT3 result in abnormal heart rhythms during sleep.

Individuals with LQT4 have the typical cardiac dysfunction seen in LQTS: slow heartbeat (sinus node bradycardia) leading to the abnormal function of the body's natural pacemaker (sinus node dysfunction), severely abnormal heartbeat of the lower heart chambers (ventricular fibrillation), rapid heartbeat (ventricular tachycardia), episodes of severely abnormal heartbeat in the heart's

KEY TERMS

Action potential—The wave-like change in the electrical properties of a cell membrane, resulting from the difference in electrical charge between the inside and outside of the membrane. The action potential acts as a signal for certain activities and processes in the body.

Arrhythmia—Abnormal heart rhythm; examples are a slow, fast, or irregular heart rate.

Beta-adrenergic blocker—A drug that works by controlling the nerve impulses along specific nerve pathways.

Caveolae (singular, caveola)—Tiny, flask-shaped pockets in the plasma membranes of human and animal cells.

Depolarization—The dissipation of an electrical charge through a membrane. In the heart, depolarization causes the heart muscle to contract.

Electrocardiogram (ECG, EKG)—A test used to measure electrical impulses coming from the heart in order to gain information about its structure or function.

Fibrillation—A rapid, irregular heartbeat.

Ion channel—Cell membrane proteins that control the movement of ions into and out of the cell.

QT interval—The section on an electrocardiogram between the start of the QRS complex and the end of the T wave, representing the firing or depolarization of the ventricles and the period of recovery prior to repolarization, or recharging, for the next contraction.

Repolarization—Period when the heart cells are at rest, preparing for the next wave of electrical current (depolarization).

Syncope—A brief loss of consciousness caused by insufficient blood flow to the brain.

Tachycardia—An excessively rapid heartbeat; a heart rate above 100 beats per minute.

Torsades de pointes (TdP)—Term that means turning of the points in French; a type of fast heartbeat or tachycardia of the ventricles that is characteristic of long QT syndrome.

upper chambers (atrial fibrillation) in adulthood (though not childhood), and risk of sudden death. However, a long QT interval is not always seen in individuals with LQT4, so it is considered a condition distinct from classical long QT syndromes. Individuals with some of the

variants of the *KCNE2* gene that cause LQT6 may be adversely affected by exercise and some medications.

Individuals with LQT7 are affected by episodes in which they cannot move (potassium-sensitive periodic paralysis), heart problems, and unusual face and body features. The symptoms of LQT7 can include short stature, wide-spaced eyes (hypertelorism), low-set ears, small chin (hypoplastic mandible), palate abnormalities, curved fingers and toes (clinodactyly), fused fingers and toes (syndactyly), curved back (scoliosis), periodic paralysis, long QT interval, abnormal heartbeat in the upper and lower chambers of the heart, rapid heartbeat, and sudden death.

Long QT syndrome with syndactyly is characterized by symptoms in multiple parts of the body that include lethal heart arrhythmias, webbing of fingers and toes (syndactyly), heart defects present at birth, immune deficiency, severe low blood sugar that comes and goes, developmental delays, and autism.

Diagnosis

A diagnosis of LQTS most often comes from an electrocardiogram (ECG or EKG). An ECG records the electrical activity of the heart using electrical leads placed at specific sites on the body. The electrical activity due to the depolarization and repolarization of the heart is recorded by each lead and added together. The recordings, on paper or on a monitor, show a series of peaks, valleys, and plateaus.

The QRS complex is a sharp peak and dip on the ECG that occurs as the electrical impulses fire the cells of the ventricles, causing contraction and depolarization of the action potential. The *torsades de pointes* (turning of the points) refers to these spikes in the QRS complex. Sometimes it is possible to diagnose *torsades de pointes* from an ECG. The T wave on the ECG occurs as the cells recover and prepare to fire again with the next heartbeat. Thus, the T wave represents the repolarization of the ventricles. The QT interval on the ECG is the period from the start of the depolarization of the ventricles (Q), as the electrical current traverses the ventricles from the inside to the outside, through the repolarization of the ventricles (T), as the current passes from the outside to the inside. The QT interval represents the firing and recovery cycle of the ventricles. In LQTS, the QT interval on the ECG may be a few one-hundredths of a second longer than normal. A QT interval that is longer than 440 milliseconds is considered to be prolonged. There also may be abnormalities in the T wave of the ECG.

ECGs may vary depending on the specific mutation that is the cause of the LQTS. Furthermore, up to 12% of individuals with LQTS may show normal-appearing or

borderline-normal QT intervals. An individual's ECGs can vary from reading to reading, and additional ECGs or ECGs performed during exercise may reveal an abnormal QT interval. ECGs of parents or siblings may contribute to a diagnosis, since one parent, and possibly siblings, may carry a gene variation that causes LQTS and therefore may exhibit a prolonged QT interval on an ECG.

Children with LQTS may exhibit a low heart rate; specifically, a resting heart rate that is below the second percentile for their age. A fast heart rate of 140–200 beats per minute may indicate tachycardia resulting from LQTS. Convulsive seizures due to LQTS sometimes are misdiagnosed as epilepsy, particularly in children. Some individuals with LQTS may have low levels of potassium in their blood.

Some individuals with LQTS may be identified by the combination of the standard diagnostic measurement with ECG and physical examination. Long QT syndrome with syndactyly, LQT7, and Jervell and Lange-Nielsen syndrome have such features as a hearing impairment, fused fingers, or facial features that may lead to a diagnosis.

Currently, there is no single specific diagnostic test that can identify all cases of LQTS. The difficulty in developing a comprehensive test is due to the fact that more than 200 specific changes in many different genes have been found to be responsible for LQTS. Additionally, approximately half the individuals diagnosed with LQTS do not carry any of the known genetic variations. However, when family members are known to carry a specific LQTS gene mutation, genetic testing may be used to diagnose LQTS in other family members. As of 2015, molecular genetic testing was available for all types of long QT syndrome except types 4, 7, and 8.

Treatment and management

Beta-adrenergic blockers, or beta-blockers, are the most common treatment for the ventricular arrhythmia resulting from LQTS. Propranolol is the most frequently prescribed drug. It lowers the heart rate and the strength of the heart muscle contractions, thereby reducing the oxygen requirement of the heart. Propranolol also regulates abnormal heart rates and reduces blood pressure. Other beta-blockers prescribed for patients with LQTS include atenolol, metoprolol, and nadolol.

Approximately 90% of individuals with LQTS can be treated successfully with these drugs. Since the prophylactic effects disappear within one or two days of stopping the beta-blocker, treatment with these drugs usually lasts for life. Since the first symptom of LQTS may be sudden death, younger individuals with prolonged QT intervals or with family histories of LQTS are commonly treated with beta-blockers, even in the absence of symptoms.

QUESTIONS TO ASK YOUR DOCTOR

- What does the acronym QT mean in the term “long QT syndrome”?
- What are the primary medical problems to be concerned about for a child diagnosed with long QT syndrome?
- What medications are recommended for use with a child with long QT syndrome?
- What is the prognosis for a person with long QT syndrome?

Beta-blockers are considered to be safe medications. Any side effects from propranolol are usually mild and disappear once the body has adjusted to the drug. However, propranolol and other beta-blockers can interact dangerously with many other medications.

As knowledge of the causes of LQTS increases, other drugs may prove to be more effective for treating some forms of LQTS. For example, mexiletine, a sodium-channel blocker, is used to shorten the QT interval in individuals with LQT3 that results from mutations in the *SCN5A* gene.

Elevating the levels of blood potassium may relieve symptoms of LQTS in individuals with mutations in potassium channel genes. For example, increased blood potassium raises the outward potassium current in the *hERG*-encoded channel. Thus, treatment with potassium can compensate to some extent for the shortage of functional potassium ion channels in individuals with LQT2, thereby shortening the QT interval.

Left cardiac sympathetic denervation, the surgical cutting of a group of nerves connecting the brain and the heart, may reduce cardiac arrhythmias in individuals with LQTS. Pacemakers or automatic implanted cardioverter defibrillators (AICDs) are also used to regulate the heart-beat or to detect and correct abnormal heart rhythms. Sometimes, a pacemaker or AICD is used in combination with beta-blockers.

Since the likelihood of developing symptoms of LQTS after about age 45 is quite low, individuals who are at least middle-aged when first diagnosed may not be treated. However, all individuals that have been diagnosed with LQTS must avoid reductions in blood potassium levels, such as those that occur with the use of diuretic drugs. Additionally, individuals with LQTS must avoid a very long list of drugs and medications that can

increase the QT interval or otherwise exacerbate the syndrome.

Infants in LQTS families should be screened with ECGs and monitored closely due to the 41-fold increase in the risk of SIDS.

Individuals with LQTS usually are advised to refrain from competitive sports and to have someone around them during moderate exercise. Family members may be advised to learn cardiopulmonary resuscitation (CPR) in case of cardiac arrest.

Individuals with LQTS require special attention and careful management before, during, and after surgery. Recommendations include monitoring baseline QT interval, using adequate amounts of beta-blocker medications, maintaining a quiet and calm environment, preparing a defibrillator to be available for immediate use, using premedications as needed, ensuring the patient is adequately anesthetized before laryngoscopy and tracheal intubation to avoid sympathetic stimulation, and using of topical anesthesia before intubation. During the operation, recommendations include monitoring the QT interval, keeping a quiet and calm environment, and avoiding patient hypothermia. Specific agents are recommended to be used for general anesthesia, including propofol for induction or as continuous infusion throughout, isoflurane as volatile agent of choice, vecuronium for muscle relaxation (dose appropriately to avoid pharmacologic reversal), and fentanyl for analgesia. After surgery, careful monitoring of the patient and his or her QT interval is recommended until the patient has recovered from anesthesia and the monitored QT interval has returned to baseline. It is also recommended to ensure adequate pain control after surgery.

Prognosis

The prognosis usually is quite good for LQTS patients who receive treatment; only 4%–5% of cardiac events were fatal as of 2015. Symptoms may disappear completely and, often, at least some of the ECG abnormalities revert to normal. In contrast, the death rate for LQTS can be very high among untreated individuals.

Women with LQTS usually do not experience an increase in cardiac events during pregnancy or delivery. However, they may experience an increase in serious episodes of irregular heartbeat in the months following delivery. This is especially true for women who have experienced syncopic episodes prior to pregnancy. This increase in symptoms may be due to the physical and emotional stress of the postpartum period. Women who receive beta-blocker therapy during pregnancy and following delivery experience far fewer cardiac events. Beta-blockers do not appear to adversely affect a pregnancy, nor do they appear to harm the fetus.

Lowe oculocerebrorenal syndrome

Definition

Lowe oculocerebrorenal syndrome is a rare genetic condition that affects males. It is caused by an enzyme deficiency, and affects many body systems including the eyes, the kidneys, and the brain.

Lowe syndrome: pedigree analysis chart (Gale)

Description

Lowe oculocerebrorenal syndrome was first described by Dr. Charles Lowe in 1952. The syndrome is caused by a change (mutation) in the *OCRL1* gene. This gene is responsible for the production of the enzyme phosphatidylinositol 4,5-bisphosphate 5-phosphatase. A mutation in the *OCRL1* gene leads to a decrease in enzyme activity. This decrease in the activity of phosphatidylinositol 4,5-bisphosphate 5-phosphatase is responsible for the physical and mental problems associated with Lowe oculocerebrorenal syndrome. The reason a deficiency of this enzyme causes Lowe oculocerebrorenal syndrome is still unknown. Phosphatidylinositol 4,5-bisphosphate 5-phosphate phosphatase is thought to be limited to a specific part of the cell called the Golgi apparatus. The relationship between the function of the Golgi apparatus, the enzyme deficiency, and the features of Lowe oculocerebrorenal syndrome is unclear.

The name Lowe oculocerebrorenal syndrome describes the body systems most commonly affected by this genetic disease. The term “oculo” refers to the eye problems commonly seen in individuals with the disease. Cataracts (cloudiness of the lens of the eye) are a classic feature and are usually present at birth (congenital). Other eye problems are also common. The term “cerebro” refers to the brain dysfunction commonly seen in the disease. The majority of affected males have intellectual disabilities and behavior disturbances. The term “renal” refers to the associated kidney problems, which can interfere

with normal bone development and eventually lead to kidney failure.

Genetic profile

Changes (mutations) in the *OCRL1* gene decrease the activity of the enzyme phosphatidylinositol 4,5-bisphosphate 5-phosphatase. There have been many different mutations identified in the *OCRL1* gene. These mutations may be different between families. The *OCRL1* gene is located on the X chromosome. Since the *OCRL1* gene is located on the X chromosome, Lowe oculocerebrorenal syndrome is considered to be X-linked. This means that it only affects males.

A person’s sex is determined by his or her chromosomes. Males have one X chromosome and one Y chromosome, while females have two X chromosomes. Males who possess a mutation in their *OCRL1* gene will develop Lowe oculocerebrorenal syndrome. Females who possess a mutation in their *OCRL1* gene will not; they are considered to be carriers. This is because females have another X chromosome without the mutation that allows normal function, and prevents them from getting this disease. If a woman is a carrier, she has a 50% risk during pregnancy of passing on her X chromosome with the mutation. Therefore, with every male pregnancy, she has a 50% risk of having an affected son, and with every female pregnancy, she has a 50% risk of having a daughter who is a carrier.

Demographics

Lowe oculocerebrorenal syndrome affects approximately 1 in 100,000 live births. It occurs evenly among ethnic groups. Almost always, only male children are affected. Women carriers usually do not have physical or mental problems related to the disease.

Signs and symptoms

The signs and symptoms of Lowe oculocerebrorenal syndrome are variable. Some individuals with Lowe oculocerebrorenal syndrome have many severe symptoms, while other affected individuals have fewer, more mild symptoms.

Eye problems are a common feature of Lowe oculocerebrorenal syndrome. Congenital cataracts are a classic feature of the disorder. These cataracts may be one of the first symptoms noticed during infancy. Approximately 50% of males with Lowe oculocerebrorenal syndrome will develop increased pressure behind the eye (glaucoma). This pressure can damage the eye. Other eye problems include strabismus (crossed or divergent eyes), nystagmus (uncontrollable rhythmic eye movements), and microphthalmia (small eyes).

The nervous system (brain and nerves) is also typically affected by Lowe oculocerebrorenal syndrome. Intellectual disability is a common feature of Lowe oculocerebrorenal syndrome. It can vary between mild and severe. Some males with Lowe oculocerebrorenal syndrome have normal intelligence. Seizures and behavior disturbances can also be seen in individuals with Lowe oculocerebrorenal syndrome. Behavior disturbances can include temper tantrums, aggression, obsessions, and repetitive hand movements. One of the first signs of brain dysfunction caused by Lowe oculocerebrorenal syndrome is muscle weakness (hypotonia) during infancy.

Kidney problems are another common finding in individuals with Lowe oculocerebrorenal syndrome. The kidneys normally filter chemicals and acids from the body. The kidneys allow the body to keep needed substances and to remove unneeded substances through the urine. Individuals with Lowe oculocerebrorenal syndrome cannot do this properly, allowing needed substances (calcium, phosphate, etc.) to be excreted in the urine. This kidney disturbance can ultimately lead to kidney failure.

Individuals with Lowe oculocerebrorenal syndrome frequently have slow growth and a short stature. Problems with bones can also develop due to the loss of

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Cataract—A clouding of the eye lens or its surrounding membrane that obstructs the passage of light, resulting in blurry vision. Surgery may be performed to remove the cataract.

Cerebro—Related to the head or brain.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance, a needle is inserted through either the mother's vagina or abdominal wall and a sample of cells is collected from around the fetus. These cells are then tested for chromosome abnormalities or other genetic diseases.

Congenital—Refers to a disorder that is present at birth.

Germ line mosaicism—A rare event that occurs when one parent carries an altered gene mutation that affects his or her germ line cells (either the egg or sperm cells) but is not found in the somatic (body) cells.

Glaucoma—An increase in the fluid eye pressure, eventually leading to damage of the optic nerve and ongoing visual loss.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Nystagmus—Involuntary, rhythmic movement of the eye.

Oculo—Related to the eye.

Renal—Related to the kidneys.

Rickets—A childhood disease caused by vitamin D deficiency, resulting in soft and malformed bones.

Strabismus—An improper muscle balance of the ocular muscles, resulting in crossed or divergent eyes.

certain substances through the kidneys. Rickets and easily breakable bones are common features. Joints may become inflamed in individuals with Lowe oculocerebrorenal syndrome.

Diagnosis

The diagnosis of Lowe oculocerebrorenal syndrome is based initially on the presence of the symptoms of the disorder. Lowe oculocerebrorenal syndrome is definitively diagnosed by measuring the activity of the enzyme phosphatidylinositol 4,5-bisphosphate 5-phosphatase. When the activity of this enzyme is very low, it is diagnostic of Lowe oculocerebrorenal syndrome. In order to perform this test, a small piece of skin must be removed from the patient's body (skin biopsy). The enzyme is then measured from cells in this skin sample. In some cases it is also possible to look for a mutation in the *OCRL1* gene. The presence of mutation confirms the diagnosis of Lowe oculocerebrorenal syndrome in males.

Determining if a woman is a carrier of Lowe oculocerebrorenal syndrome can be done several different ways. Females who carry a mutation in their *OCRL1* gene commonly have changes in the lens of the eye. These changes can only be detected by an ophthalmologist with a special eye examination. These changes do not cause vision problems. The eye difference seen in carriers of Lowe oculocerebrorenal syndrome is best observed once females reach adulthood. Recent reports suggest that a detailed eye exam can detect 90% of carriers. In addition to eye examinations, carrier detection can be performed with DNA testing. If the *OCRL1* mutation has been identified in an affected male in the family, the females in the family can undergo DNA testing.

Prenatal diagnosis is possible by measuring the activity of phosphatidylinositol 4,5-bisphosphate 5-phosphatase in fetal tissue drawn by amniocentesis or chorionic villus sampling. In cases where the mutation is known, DNA testing can be used in prenatal diagnosis. Fetuses should be tested if the mother is a carrier of Lowe oculocerebrorenal syndrome. A woman is at risk of being a carrier if she has a son with Lowe oculocerebrorenal syndrome or someone in her family with Lowe oculocerebrorenal syndrome. Any woman at risk of being a carrier can undergo testing to determine if she is at risk to have a son with Lowe oculocerebrorenal syndrome.

Treatment and management

There is currently no cure for Lowe oculocerebrorenal syndrome. Individuals with Lowe oculocerebrorenal syndrome benefit from therapies and regular medical care. Physical therapy, occupational therapy, and speech therapy may be recommended due to developmental delays. Regular eye exams by an ophthalmologist are also recommended. Patients with Lowe oculocerebrorenal syndrome should be seen by a nephrologist (kidney doctor). Dialysis may ultimately be recommended for kidney failure.

Prognosis

The lifespan of males with Lowe oculocerebrorenal syndrome is limited by their multiple medical problems. Death by middle age is common. However, medical advances are improving the quality of life for individuals with this genetic condition.

Lupus

Definition

Lupus refers to a large group of complex autoimmune disorders in which the immune system attacks and damages or destroys the body's own cells and tissues. The most common type of lupus is systemic lupus erythematosus (SLE), which can affect many different parts of the body. The Lupus Foundation estimates that as many as 1.5 million Americans have lupus, and most are women of childbearing age. Variations in a number of

Lupus is an autoimmune disease that can affect various parts of the body. (Gwen Shockey/Science Source)

different genes have been implicated in a susceptibility to SLE. As a result, SLE is a particularly complex and varied disorder. It has both hereditary and environmental risk factors. For example, according to author Daniel J. Wallace, environmental risk factors that may trigger lupus include exposure to tobacco smoke; some viruses, especially Epstein-Barr; and exposure to substances such as crystalline silica. In addition, there is probable environmental association to heavy metals and pesticides.

Description

The immune system normally protects the body from foreign organisms and other substances. By contrast, lupus is a disorder in which immune system components

attack the healthy cells and tissues. Lupus is a complex disorder that can damage skin, joints, blood vessels, and internal organs, including the kidneys, heart, lungs, and brain.

SLE is a chronic disorder that causes inflammation of the connective tissues, such as cartilage and the lining of blood vessels. Kidney disease occurs in about one-third of patients with SLE. SLE can cause various heart problems, such as pericarditis (inflammation of the membrane enclosing the heart) or heart valve abnormalities. People with SLE are also prone to heart disease from atherosclerosis (the buildup of fat and plaque in the blood vessels). Inflammation from SLE can damage the nervous system, causing a variety of problems, including

peripheral neuropathy (weakness and pain in the limbs), seizures, stroke, and cognitive impairment that affects memory, learning, and reasoning. Anxiety and depression are common with SLE. As a result of these multiple health risks, patients with SLE or other forms of lupus need to see their primary care physicians on a regular basis to manage their symptoms.

Other types of lupus include the following:

- discoid lupus erythematosus that causes a chronic rash
- subacute cutaneous lupus erythematosus that results in sores after exposure to sunlight
- medication-induced lupus, which many drugs may trigger, such as hormones, antibiotics, anticonvulsants, lithium, and other drug categories
- neonatal lupus, a rare form affecting newborns

Causes

The cause of lupus is not known, but the disorder appears to stem from a combination of genetic factors that contribute to a susceptibility to the disorder as well as to environmental factors or triggers. Sex hormones appear to

play a role in triggering lupus. Environmental factors can include diet, stress, chemical exposure, sunlight, and viral infections. About 10% of SLE cases appear to be triggered by drug exposure, and more than 80 different drugs that can trigger SLE have been identified.

A characteristic of SLE is that cells that have self-destructed (undergone apoptosis)—either because they are damaged or have reached the end of their functional lifespan—are not properly eliminated from the body. It has been suggested that these dead cells may release substances that trigger improper immune system reactions.

Another possible cause is a specific type of immune cell. In a study reported by the National Institutes of Health (NIH) in 2020, researchers identified two types of dysregulated neutrophils that appeared to be implicated in lupus. Neutrophils are white blood cells active in the immune system. Researchers have found two types of low density granulocytes (LDGs) present in some neutrophils that may be implicated in the disease process, including one set that lacks a substance known as C10 and another more mature set that includes CD10. The researchers found that the higher levels of CD10-

A person's hands displaying signs of lupus. (*Biophoto Associates/Science Source*)

positive LDGs from the more mature subpopulation of neutrophils isolated from the blood of lupus patients correlated with more severe organ damage and reduced kidney function. This finding may help scientists develop clinical biomarkers so they can more aggressively treat lupus patients with higher numbers of these mature LDGs. The hope is that a path will also be found enabling researchers to decrease the abnormal actions of these problematic neutrophils.

Genetic profile

Lupus, especially SLE, and other autoimmune disorders appear to run in families. Normal variations, known as polymorphisms, in at least 17 different genes are known to increase the risk of SLE. Thus, the genetic contributions to the development of SLE and perhaps other types of lupus are complex. In most cases, people with SLE do not inherit a gene that causes the disorder; rather, they inherit variations in genes that increase the risk of developing the disorder under the influence of other factors or triggers. Most genes that have been associated with SLE are involved in the functioning of the immune system, and SLE-associated variations in these genes may affect the control and specific targeting of the immune response.

Rarely, SLE is caused by autosomal recessive mutations in the *TREX1* gene. *Autosomal recessive* means that an individual must inherit two mutated copies of the *TREX1* gene, one from each parent, to develop SLE. The parents, each carrying one copy of the mutant gene, do not have signs and symptoms of SLE. Mutations in *TREX1* can also cause a rare form of SLE called chilblain lupus that primarily affects the skin. *TREX1* encodes a protein called an exonuclease that breaks down DNA so that it can be repaired. *TREX1* mutations also cause disorders other than lupus.

Demographics

Although lupus can affect anyone, women are more often affected, representing about 90% of all lupus cases. Nonwhite women, especially African American, Hispanic, Asian, and Native American women, have a greater risk for lupus than white women. For example, African American women are three times more likely to develop lupus compared to white women. Non-white women usually develop lupus at a younger age and develop more severe medical problems, such as kidney issues, than white women. Although SLE is more common among younger women, 20% of cases occur in people over age 50. Symptoms of SLE vary greatly and can resemble signs and symptoms of other disorders, so SLE may be underdiagnosed. Nevertheless, the prevalence of

SLE increased ten-fold in the industrialized West from 1970 to 2020, for reasons that are unclear.

Some researchers have found that lupus has been greatly underestimated as a cause of death, which in turn underestimates the burden of the disease on individuals as well as society at large. For example, in a study in Sweden in 2017, Titilola Falasinnu and colleagues compared data from more than 8,000 people with lupus and found that of 1,802 deaths among patients with SLE, more than half (59%) had no report of SLE listed in their death records. Individuals ages 85 years and older were least likely to have SLE listed as a cause of death. The researchers noted that in three of five patients who died with SLE, there was no report of the SLE diagnosis. The researchers said others have seen similar findings, and this factor accounts for the underreporting of rare diseases such as SLE. The researchers found that the primary cause of death among those who died with SLE was cardiovascular disease (ICVS); however, for most people with lupus, the cause of their CVD is the SLE itself.

Signs and symptoms

Signs and symptoms of lupus vary greatly. Symptoms are often intermittent, with flare-ups that range from mild to severe, or the development of new symptoms. Common symptoms include the following:

- joint swelling or pain
- muscle pain
- fever
- red rashes, especially on the face
- hair loss
- swollen glands
- chest pain when breathing deeply
- pale or purple fingers or toes
- sensitivity to sunlight
- swelling in the legs or around the eyes
- mouth or nose sores
- fatigue

Other symptoms can include the following:

- low red blood cell count (anemia)
- headaches
- dizziness
- sadness
- confusion
- seizures

Additional symptoms of SLE can vary greatly because so many different organs may be affected. Initial symptoms may include fatigue, malaise, fever, loss of appetite, and weight loss. Joint pain affects most people

with SLE, usually in the same joints on both sides of the body. Muscle pain and weakness also affect many patients. Skin rashes are common, especially a flat red rash, called a butterfly rash, across the bridge of the nose and cheeks. Other skin problems include calcium deposits under the skin (calcinosis), tiny red spots called petechiae from bleeding under the skin due to a lack of platelets for clotting, and damaged blood vessels under the skin (vasculitis).

Diagnosis

Lupus can be difficult to diagnose; it often takes months or years to reach a diagnosis. A medical history, complete physical exam, blood tests, and biopsy of the skin and/or kidney for examination under a microscope may all contribute to the diagnosis.

A blood test called an antinuclear antibody panel is an important component of diagnosis. It tests for the presence of antinuclear antibodies (ANA), which are immune-system antibodies that attack the body's own tissues in autoimmune disorders, especially SLE. Although healthy people may have low levels of ANA, high levels are suggestive of SLE or another autoimmune disorder. High amounts of ANA in the blood are particularly suggestive of SLE if antibodies against double-stranded DNA are also present. Some researchers also suggest considering other biomarkers for SLE; for example, Benoit Brillard and colleagues in France found in their study of 109 patients with SLE and 47 healthy controls, the levels of interleukin-1 (IL-1) were significantly higher in the patients with SLE compared to the controls. These levels were also higher in patients with SLE with active symptoms compared to those whose symptoms were not active.

Treatment and management

The goals of lupus management are to prevent flare-ups, treat flare-ups when they occur, and reduce the risks for organ damage and other complications of SLE. Treatment may include various medications for reducing pain and swelling, preventing or reducing flare-ups, suppressing the immune system, reducing or preventing damage to joints, and balancing hormones. Drugs to reduce cholesterol levels and blood pressure or prevent or treat infection may also be necessary.

Drugs

Anti-inflammatory medications are the most common lupus drugs, and for many people they are the only treatment required. Anti-inflammatories reduce inflammation and pain and can quickly relieve fever or arthritis. These drugs include aspirin, acetaminophen (Tylenol), or

KEY TERMS

Allele—One of two or more different genes encoding specific and inheritable characteristics that occupy corresponding locations on a pair of chromosomes.

Antibody—A protein produced by the mature B cells of the immune system that attach to invading microorganisms and target them for destruction by other immune system cells.

Antinuclear antibodies (ANAs)—Abnormal antibodies against cell nuclei. They are found in the blood of people with autoimmune diseases such as lupus.

Autoantibody—An antibody against the body's own proteins that the immune system produces.

Autoimmune disorder—A disorder that occurs when the body's tissues are attacked by its own immune system, as in RA.

Autosomal recessive—A pattern of genetic inheritance in which two abnormal genes are needed to display the trait or disease.

Monoclonal antibody (mAB)—A protein, produced in large quantities in a laboratory, designed to attack a specific target in the body.

Nonsteroidal anti-inflammatory drug (NSAID)—A pain reliever, such as ibuprofen or naproxen.

Polymorphism—A change in the base pair sequence of DNA that may or may not be associated with a disease.

Systemic lupus erythematosus (SLE)—A chronic, inflammatory autoimmune disorder that is the most common type of lupus.

nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen, naproxen, indomethacin, nabumetone, or celecoxib. Corticosteroids (glucocorticoids, cortisone, and steroids) are drugs that function like the hormone cortisol in the body to decrease inflammation, regulate blood pressure, and suppress the immune system. Prednisone is the most common corticosteroid prescribed for lupus. Prednisolone or methylprednisolone may be prescribed for patients with liver problems. Steroids are usually taken as pills, but they can also be injected into muscles, joints, or skin lesions or administered intravenously over a period of several hours (pulse steroids) so that the effects last for weeks to control a flare-up. Topical steroid creams or gels are used for skin symptoms. Steroids are usually taken only during lupus flares, in gradually reduced dosages, or intermittently, because of

QUESTIONS TO ASK YOUR DOCTOR

- Why do you think I might have lupus?
- How is lupus diagnosed?
- Can I have genetic testing for lupus-associated genes?
- Could I pass lupus on to my children?
- What treatments do you recommend?

long-term complications from their use, including increased risk of infection. Antimalarial drugs such as hydroxychloroquine (Plaquenil) are given to treat cutaneous and musculoskeletal issues. If antimalarials as well as drugs such as methotrexate have no effect, then belimumab (Benlysta), a monoclonal antibody that was developed in the laboratory, may be used to suppress the immune system. A drug in the immune modulator category, voclosporin (Lupkynis), as well as belimumab, is approved to treat lupus nephritis, or kidney disease caused by lupus.

Antimalarial drugs may be used in combination with other drugs such as steroids to reduce their required doses. Antimalarials are most often used for skin rashes, mouth ulcers, and joint pain. Antimalarials decrease auto-antibody production and help protect against ultraviolet radiation from sunlight. Hydroxychloroquine (Plaquenil) or chloroquine (Aralen) are most often prescribed for lupus skin rashes and joint pain.

Immunosuppressives or immune modulators are used to control inflammation from an overactive immune system, especially when steroids cannot control symptoms. These drugs can significantly increase the risk of infection. Immunosuppressives used for lupus include azathioprine and the anticancer drugs cyclophosphamide and methotrexate.

Anticoagulants help prevent blood clots, which can be a life-threatening symptom of lupus. Anticoagulants include low-dose aspirin, heparin, and warfarin. Anticoagulant therapy may be continued for life. Variations in two genes may affect responses to warfarin, and people with particular variations in these genes may need lower doses.

Belimumab (Benlysta) is a monoclonal antibody (mAB) that prevents the activation of immune-system B cells by interfering with a protein called BLyS that is required for B-cell activity. It was the first drug developed and approved specifically for treating lupus.

Prognosis

Because lupus, especially SLE, comprises such a varied group of disorders, prognosis is difficult. Infection is one of the leading causes of death in people with lupus. SLE usually occurs in episodes of flares or exacerbations and remissions (when symptoms lessen or disappear). In general, however, SLE worsens over time, and organ damage may become life-threatening.

Lynch cancer family syndrome see **Hereditary colorectal cancer**

Lynch syndrome

Definition

Lynch syndrome, also known as hereditary nonpolyposis colorectal cancer (HNPCC), is a family cancer syndrome caused by a germline mutation and characterized by a sharply increased risk of developing cancer of the colon and rectum. Cancers of the colon and rectum are termed colorectal cancer and are potentially life-threatening tumors that develop in the large intestine. Most cases of colorectal cancer (about 95%) are sporadic, however, rather than hereditary; Lynch syndrome accounts for only 3%–5% of cases. The syndrome is named for Henry Lynch, the American physician who first described it in 1966 and originally termed it “cancer family syndrome.”

Description

Lynch syndrome is the name given to one of several inherited cancer susceptibility syndromes that sharply increase the risk of developing cancer of the large intestine (colon) and the rectum (the last several inches of the colon). About two-thirds of cases of colorectal cancer attributable to the syndrome begin in the proximal colon (the ascending or beginning portion of the colon located in the right side of the abdomen) as opposed to the distal colon closer to the rectum.

Generally, colon cancers start out as small benign polyps, which over time become cancerous. The most commonly occurring type of polyp with the potential to become cancerous is called an adenoma. Because patients with Lynch syndrome do develop adenomatous polyps, the term “nonpolyposis” in its alternate name is somewhat misleading. In fact, the rapid progression from benign polyps to cancerous tumors, which is known as

3D colonoscopy image showing the location of a cancerous growth (center right) in the colon of a 59-year-old patient. (Zephyr/Science Source)

accelerated carcinogenesis, is one of the key features of Lynch syndrome.

With Lynch syndrome, there is an increased rate of progression from benign polyps to cancer because the rate of genetic mutation in the affected cells is two to three times higher than in normal cells. For example, other types of colon cancer may develop over the course of eight to ten years, while in persons with Lynch syndrome, the progression from benign polyps to cancerous ones may occur within two to three years.

Persons with Lynch syndrome are also at increased risk of developing other cancers, especially of the female reproductive tract (endometrial and ovarian cancers) as well as stomach, small bowel, hepatobiliary tract (the liver, gall bladder, and bile ducts), pancreas, urinary tract, and brain cancers. The lifetime estimated risks (the risk of developing a disease during the course of a lifetime) for these cancers in persons with Lynch syndrome are as follows: endometrial (40% by age 70); ovarian (9%–12%); gastric (2%–13%); urinary tract (1%–12%); small bowel (4%–7%); brain (1%–4%); and hepatobiliary (2%). Because of this increased risk of developing cancers outside the large intestine, some experts divide Lynch syndrome into two types: Lynch syndrome I, characterized by hereditary colon cancer; and Lynch syndrome II, associated with other cancers of the reproductive system and gastrointestinal tract.

Genetic profile

Lynch syndrome results from an inherited germline mutation (the presence of an altered gene in the egg or

sperm that can be passed from one generation to the next) in genes that normally protect against the development of cancer by working to repair the body's DNA. There are at least seven genes whose mutations may result in Lynch syndrome: *MLH1* on the short arm of chromosome 3 at 3p21.3, *MSH2* on the short arm of chromosome 2 at 2p21, *MSH6* on the short arm of chromosome 2 at 2p16, *PMS2* on the short arm of chromosome 7 at 7p22, *PMS1* on the long arm of chromosome 2 at 2q32.2, *MSH3* on the long arm of chromosome 5 at 5q14.1, and the *EPCAM* gene, which lies next to the *MSH2* gene on chromosome 2.

The first six genes are genes that recognize and correct errors that occur during DNA replication that have been found to cause Lynch syndrome. Called *mismatch repair genes* or *MMR* genes, these genes are involved in maintaining the integrity of DNA. They check for, correct, and repair mistakes made when DNA is replicated in preparation for cell division. A mutation in any one of these genes prevents the repair of DNA replication errors. When DNA replication mistakes are not corrected, abnormal cells are produced. As these abnormal cells continue to divide, the risk of the kind of uncontrolled cell growth that can cause cancer increases. Mutations in the seventh gene, the *EPCAM* gene, cause the *MSH2* gene to be inactivated or "turned off," thus preventing the *MSH2* gene from performing DNA mismatch repair.

Mutations in the *MLH1* and *MSH2* genes are responsible for the vast majority (90%) of mutations in families with Lynch syndrome. Mutations in *MSH6* account for about 7%–10% of families with Lynch syndrome, and mutations in *PMS2* affect less than 5% of families with the syndrome. Cases resulting from mutations in the *PMS1* and *MSH3* genes are very rare.

Lynch syndrome is most often transmitted in an autosomal dominant manner, which means that it takes just one abnormal gene from one parent for the offspring to inherit the disease; or in this case, the syndrome. An affected parent has a 50% chance of passing a mutated gene to the offspring, so each child of the affected parent has a 50% chance of inheriting the mutation. Individuals with Lynch syndrome are born with a normally functioning gene on one chromosome and a mutated gene on the other chromosome.

Although most people with a gene mutation associated with Lynch syndrome have a family history of cancer, not all have a parent with cancer. This is the case because of incomplete penetrance, which means that not all mutation carriers will express the symptoms of the disease; or in this case, increased risk of developing cancer. In addition to variable or incomplete penetrance, other factors influence the development of and susceptibility

KEY TERMS

Colectomy—Surgical removal of the colon.

DNA mismatch repair—A system for recognizing and replacing wrongly paired (mismatched) nucleotide bases during DNA replication. The system can also repair some forms of DNA damage.

Germline mutation—A mutation that occurs within a germ cell (cell that gives rise to a sperm or ovum) and can be passed on to offspring.

Microsatellite instability (MSI)—An abnormally high rate of change in repeated short sequences of DNA (microsatellites) that indicates impairment of DNA mismatch repair.

Penetrance—In genetics, the proportion of persons carrying a specific genotype (genetic makeup) who express the associated phenotype (external appearance or characteristics).

Polyp—An abnormal tissue growth arising from a mucous membrane. The formation of an unusually large number of polyps is called polyposis.

Prophylactic—Referring to a medical or surgical intervention intended to prevent rather than treat disease.

Protocol—A set of guidelines for medical tests or treatments.

Sporadic cancer—A cancer that occurs at random in the population with no known cause.

Tumor—An abnormal growth of cells. Tumors may be benign (noncancerous) or malignant (cancerous).

to a disease, so while mutations in the mismatch repair genes linked to Lynch syndrome predispose individuals to cancer, it is important to observe that not all people who carry these mismatch repair gene mutations will develop cancer.

Demographics

The American Cancer Society (ACS) estimates that 93,090 new cases of colon cancer and 39,610 new cases of rectal cancer will be diagnosed in the United States in 2015, with 49,700 deaths resulting from these cancers. Lynch syndrome accounts for between 3% and 5% of these cases, or about 7,500 new cases in an average year. People with Lynch syndrome have an 80% chance of developing colorectal cancer and are at increased risk of cancers of the stomach, small intestine, kidney, pancreas,

brain, bile duct, and urinary tract. Women with Lynch syndrome are at increased risk of endometrial and ovarian cancer. Although Lynch syndrome occurs in all racial and ethnic groups worldwide, Asians with Lynch syndrome are at increased risk of stomach cancer.

Families affected by Lynch syndrome have more cases of colon cancer than would generally be expected. Furthermore, these colon cancers as well as benign polyps (noncancerous clumps of cells or gland-like growths) in the colon usually occur at younger ages than they do in the general population. For example, in the general population, the median age (half are older and half are younger) at which colorectal cancer is diagnosed is 71; about two-thirds of colorectal cancers are diagnosed in people over age 65. In contrast, colorectal cancer associated with Lynch syndrome often occurs in younger adults and is frequently diagnosed in persons in their 40s; the median age at diagnosis is 44.

Signs and symptoms

Because the Lynch syndrome gene mutations are germline mutations, they are present in every cell in the body, cancers outside the colon may develop. Among women with Lynch syndrome who develop both colon cancer and endometrial cancer, about one-half are first diagnosed with endometrial cancer, often in their mid-40s. In some families affected by Lynch syndrome, endometrial cancer occurs more frequently than colon cancer.

There are no symptoms associated with carrying the Lynch syndrome gene mutations. Similarly, it is possible to have colorectal cancer without any symptoms. Frequently, symptoms of colorectal cancer do not appear until the disease has advanced. Furthermore, the symptoms associated with colorectal cancer may also be caused by other conditions. These symptoms include:

- abdominal distress (gas, bloating, and cramps)
- rectal bleeding or blood in stool
- changes in bowel movements, such as diarrhea or constipation, or change in consistency of stools
- unexplained weight loss and/or decreased appetite
- unexplained iron-deficiency anemia (low red blood cell count)
- weakness and fatigue

Diagnosis

The diagnosis of Lynch syndrome may be made on the basis of personal and family history but is confirmed using genetic and other laboratory testing.

QUESTIONS TO ASK YOUR DOCTOR

- Am I at risk of having Lynch syndrome with only one known relative who developed colon cancer?
- Are other members of my family at risk?
- Should I consider genetic testing for the syndrome?
- When should I have my first colonoscopy, and how often should I have one?
- What other types of screening tests will you recommend?

Examination

The first step in identifying people at risk of Lynch syndrome is for the healthcare practitioner to obtain a personal and extended family history. Individuals with a family history that includes multiple relatives with colorectal cancer, other syndrome-associated cancers, or occurrence of colorectal cancer before age 60 are generally advised to undergo genetic screening and evaluation for Lynch syndrome and to consult with a genetics counselor or medical geneticist. The results of these genetic test results can guide screening recommendations for affected individuals and their families.

Tests

Genetic testing for Lynch syndrome involves examining an individual's DNA, which is extracted from the individual's blood, to detect mutations in mismatch repair genes. Because *MLH1* or *MSH2* account for the vast majority of detectable mutations, many genetic tests examine these two genes first. However, the introduction of next-generation sequencing meant that it was possible as of 2015 to test an individual for all known Lynch syndrome genes at much lower cost than a series of single-gene tests.

When a mutation is identified, it is vitally important to perform predictive genetic testing of other family members who are at increased risk (e.g., parents, offspring, siblings) because these relatives have a 50% chance of carrying the mutation. Individuals who are found to have the mutation are advised to have earlier and more frequent intensive cancer screening.

A negative test result means that no genetic mutations were detected in the individual tested. When other family members have already tested positive for a

mutation, a negative result means the individual did not inherit the mutation. However, when the individual with a negative test result is the first family member who is tested, this finding does not necessarily mean that there is no basis for a family's higher-than-expected occurrences of cancers. The negative test result may indicate that available tests cannot pinpoint the genetic cause of a family's cancers because some of the genes responsible for the syndrome may not have been identified as of 2015.

It is also possible for genetic testing to produce an indeterminate test result, which means that a genetic variant (change) was detected but the variant detected was not one known to be associated with Lynch syndrome. In this case, it is often advisable to test other family members to determine whether the variant detected is associated with a family's higher-than-expected occurrences of cancer. In some cases, a screening test for Lynch syndrome in patients with colorectal or endometrial cancer can be performed on a sample of tumor tissue taken from the patient. The tissue sample may be tested for microsatellite instability (MSI), which means that short repeated sequences of DNA known as microsatellites are examined for indications that DNA mismatch repair is not taking place in the tumor sample. The number of microsatellites in the tumor sample is compared with the number in a sample of normal tissue from the same patient. If the number of repeats differs in the two samples, MSI is present.

The tumor tissue sample may also be tested by immunohistochemistry (IHC), a process that can be used to evaluate the proteins produced by the mismatch repair genes. If a specific protein is missing, it indicates that the gene that codes for that protein has a mutation. A combination of MSI and IHC testing is considered the most accurate way to identify cancer patients who are carriers of Lynch syndrome, and has been recommended as a screening procedure by the American Society of Clinical Oncology and the European Society for Medical Oncology.

Procedures

Enhanced cancer surveillance for individuals who test positive for Lynch syndrome (and those considered at greater risk despite negative or indeterminate test results) may consist of more frequent examinations of the colon, and prompt removal of polyps when they are present. Examination of the colon, called a colonoscopy, enables a physician to view the entire length of the large intestine using a colonoscope (a long flexible tube with a video camera on one end), which is inserted into the rectum and advanced through the intestine. During a colonoscopy, the physician may remove polyps and take a tissue sample,

which is sent to a laboratory for testing. The test is performed using a technique called immunohistochemistry, a process that involves treating a biopsy sample with antibodies that recognize cell proteins typical of certain kinds of cancers. The sample also is treated with chemicals that cause the cells containing specific proteins to change color, which allows them to be seen under a microscope.

In addition to more frequent colonoscopies, people with Lynch syndrome may be advised to have more frequent fecal occult blood tests that detect even small amounts of blood in the stool, which may indicate the presence of polyps or a tumor. When blood is detected in a stool sample, a colonoscopy is performed to pinpoint its source.

Women with Lynch syndrome may also be screened for endometrial cancer annually beginning at about age 30–35 or 5–10 years before the earliest cancer diagnosis in the family. Women who have already had children may consider having a preventive hysterectomy (surgical removal of the uterus) and bilateral salpingo-oophorectomy (removal of the fallopian tubes and ovaries) to reduce the risk of developing endometrial and ovarian cancers.

Although the frequency of screening tests may vary somewhat depending on an individual's personal and family medical history, the Amsterdam surveillance protocol recommends that persons with mutations in the *MLH1*, *MSH2*, or *MSH6* genes have colonoscopies every one to two years beginning at age 20–25; urine tests every one to two years beginning at age 30–35; and gastroscopy (visual examination of the stomach by means of a flexible viewing instrument inserted in the mouth and through the esophagus) every one to two years beginning at age 30–35. Women should have an ultrasound of the endometrium and a blood test for CA-125, a cancer marker detected in the blood, every one to two years beginning at age 30–35.

Treatment and management

Detecting and promptly removing precancerous polyps is an important way to prevent colorectal cancer from developing. This preventive measure is especially important in people diagnosed with Lynch syndrome.

When cancerous tumors are detected, portions of the colon or the entire colon may be removed to prevent the spread of the cancer. Because removing the colon is the only certain way to prevent colon cancer, some patients with Lynch syndrome choose to have a total colectomy (surgical removal of the colon) before cancer occurs. This practice, known as prophylactic surgery, is highly controversial.

Prognosis

Early identification of people with Lynch syndrome and timely screening can help to detect precancerous polyps so they may be removed. Similarly, regular screening can facilitate early detection of cancers and allow treatment to begin when it is most likely to be effective. Colorectal cancer is among the most curable cancers when it is detected and treated in its earliest stages. Further, people with Lynch syndrome who do develop colorectal cancer fare better than other patients with colorectal cancer; overall, those with the syndrome have higher rates of survival.

Macular degeneration—age-related

Definition

Age-related macular degeneration (AMD) is one of the most common causes of vision loss among adults over age 55 living in developed countries. It is caused by the breakdown of the macula, the central part of the retina located in the back of the eye. The macula allows people to see objects directly in front of them (called central vision), as well as to see fine visual details. People with AMD usually have blurred central vision and difficulty seeing details and colors, and they may notice a distortion of straight lines.

Description

Both the function of the macula and the diagnosis of AMD are best understood by considering normal eye function. The eye is made up of many layers of different types of cells that all work together to send images from the environment to the brain, similar to the way a camera records images. When light enters the eye, it passes through the lens and lands on the retina, a very thin tissue that lines the inside of the eye. The retina is made up of 10 different layers of specialized cells, which allow it to function similarly to film in a camera, by recording images. The macula is a small, yellow-pigmented area located in the center of the back of the eye on the retina. It contains blood vessels and nerve fibers. It also contains many specialized cells, called photoreceptors, that sense light coming into the eye, convert light into electrical messages, and send those messages to the brain through the optic nerve. They allow the brain to perceive the environment.

The retina contains two types of photoreceptor cells: rods and cones. The rods are located primarily outside of the macula, and they allow for peripheral (side) and night vision. Most of the photoreceptor cells inside the macula

are the cone cells, which are responsible for perceiving color and viewing objects directly in front of the eye (central vision). If the macula is diseased, as in AMD, then color and central vision are altered. There are two different types of AMD: dry AMD and wet AMD.

Dry AMD

Approximately 90% of individuals with AMD have the dry form. This condition is sometimes referred to as nonexudative, atrophic, or drusenoid macular degeneration. In dry AMD, some of the layers of retinal cells (called retinal pigment epithelium, or RPE cells) near the macula begin to degenerate. The RPE is the insulating layer between the retinal and choroid layer, which contains blood vessels. It acts as a protective shield against damaging chemicals and as a filter for the nutrients that reach the retina from the choroid blood vessels. The RPE cells normally help remove waste products from the rods and cones. When the RPE cells are no longer able to provide this function, fatty deposits called drusen begin to accumulate, enlarge, and increase in number underneath the macula. The drusen formation can disrupt the cones and rods in the macula, causing them to degenerate or atrophy (die). This usually leads to central and color vision defects for people with dry AMD. However, some people with drusen deposits have minimal or no vision loss and require regular eye examinations to check for AMD. Dry AMD is sometimes called nonexudative, because even though fatty drusen deposits form in the eye, people do not have leakage of blood or other fluid (often called exudate) in the eye. Symptoms remain stable or worsen slowly from early stages to intermediate or advanced stages of dry AMD. Advanced stages of AMD may result in vision loss. Approximately 10% of people with dry AMD eventually develop wet AMD, the advanced stage of AMD.

Wet AMD

Approximately 10% of patients with AMD have wet AMD that progressed from some stage of the dry form. This form of AMD is also called subretinal neovascularization,

Wet age-related macular degeneration. The macula is a region near the center of the retina with a high density of photoreceptors responsible for high acuity vision. In wet AMD, blood vessels from the choroid undergo angiogenesis, resulting in abnormal blood vessel growth. Excess blood and fluid proteins leak into the retina and irreversibly damage or displace photoreceptors, resulting in vision loss. (Evan Oto/Science Source)

choroidal neovascularization, exudative form, or disciform degeneration. Wet AMD is caused by leakage of fluid and the formation of abnormal blood vessels (called neovascularization) in the choroid layer of the eye. The choroid is located underneath the retina and the macula, and it normally supplies them with nutrients and oxygen. When new, delicate blood vessels form, blood and fluid can leak from them. The formation of abnormal blood vessels underneath the macula leaks enough fluid to raise the macula up and away from the back of the eye and damages it. This causes central vision loss and distortion as the macula is pushed away from nearby retinal cells. Eventually, a scar (called a disciform scar) can develop underneath the macula, resulting in severe and irreversible vision loss. Wet AMD does not have early or intermediate stages. It is considered advanced AMD and is more severe than dry AMD.

Genetic profile

AMD is a complex disorder, caused by a combination of genetic and environmental factors. Researchers have identified more than 50 sites of genetic susceptibility, particularly in the *CFH* and the *ARMS2* genes, although no genetic therapy is available as of 2021. AMD exhibits multifactorial inheritance, and many factors interact with one another and cause the condition.

The aging process is one of the strongest risk factors for developing AMD. There is also genetic heterogeneity among different families with AMD, meaning that different genes can lead to the same or similar disease among different families. Overall, it has been estimated that siblings of individuals with AMD have four times the risk of developing AMD, compared to others.

Some researchers have used deep learning (artificial intelligence) to predict the development of wet AMD. In a study by Jason Yim and colleagues, a model successfully predicted the conversion of eyes to AMD within six months. In another study, Meriam Islam and colleagues used a smart phone application to analyze vision results from 245 patients receiving treatment for AMD. In 79 percent of cases, the application produced an alarm that indicated a drop in visual acuity or a change in the central macular thickness of the eye and a need for injection therapy.

In 1998, a family in which a unique form of AMD was passed from one generation to the next was discovered. Although most families with AMD do not display an obvious inheritance pattern, this particular family's pedigree showed an autosomal dominant form of AMD. Autosomal dominant refers to a specific type of inheritance in which only one allele (one copy of a gene pair)

needs to have a mutation for the disease to develop. An affected person with an autosomal dominant condition thus has one allele with a mutation and one allele that functions properly. There is a 50% chance for this individual to pass on the allele with the mutation, and a 50% chance to pass on the normal allele to each offspring. Genetic testing revealed that the autosomal dominant gene was located on chromosome 1q25-q31, in a locus now known as the *ARMD1* gene locus. In 2004, possible AMD linkage evidence was discovered in four chromosomal regions: 1q31, 9p13, 10q26, and 17q25.

In March 2005, the National Eye Institute (NEI) described the discovery of a gene for AMD in Caucasians. AMD is significantly more common in Caucasians than in individuals of other races or ethnicities, affecting about 2.5% of white adults over age 50, compared to less than 1% each among African Americans or Hispanics. The difference increases further by age 80, when 14% of Caucasians are affected by AMD, compared to about 2% each for African Americans or Hispanics in this age group. In some individuals with AMD, eye inflammation may trigger a biological process leading to AMD. This variation is in a region of *CFH* that binds the C-reactive protein involved in inflammation. *CFH* functions as a brake on the immune system. The variation in *CFH* found in AMD causes the brake to be defective. The

CFH gene is located on chromosome 1q25-31 in the *ARMD1* locus that is repeatedly linked to AMD in family-based studies.

A second susceptibility locus for AMD located on chromosome 10q26 was also identified in 2005 and further confirmed in similar GWAS studies performed in 2006. The two genes that fall within the identified locus—*ARMS2* (LOC387715) and HtrA serine peptidase 1 (*HTRA1*)—are not as well studied as the *CFH* gene. The contribution of these two genes to AMD predisposition has not been established; however, *HTRA1* has been implicated in turnover of proteins involved in drusen formation.

The *CFH* and *ARMS2/HTRA1* gene variations account for the largest percentage of risk for AMD with a combined risk increase of 40%, but they are not an absolute determinant. Not all individuals with AMD have the *CFH* or *ARMS2/HTRA1* variants, and not all of those with the variants have AMD. In their research published in 2020, Xikun Han and colleagues discussed 21 novel genes that are present in the retinal tissue and may be involved in the causes of AMD.

Although one or two particular genes may be the main cause(s) of susceptibility for AMD, other genes or environmental factors may help alter the age of onset of

Dry age-related macular degeneration. In dry AMD, cellular debris called drusen accumulate between the retinal pigment epithelium and the choroid. As a result, photoreceptor cells in the retina can no longer receive nutrients or pass waste to the blood vessels in the choroid, resulting in damage. (Evan Oto/Science Source)

A retinal photograph showing macular degeneration.
(Memorisz/Shutterstock)

symptoms or eye defects. Studies have revealed numerous risk factors for AMD, including the following:

- obesity
- heart disease
- diabetes
- high blood pressure
- cataracts
- farsightedness
- light skin and eye color
- cigarette use
- high-fat/high-cholesterol diet
- ultraviolet (UV) exposure (sunlight)
- low levels of dietary antioxidant vitamins and minerals
- female gender

The exact amount of risk associated with many of these factors is still undetermined, though studies have consistently found a strong association between AMD and smoking. Risk factors in combination with a family history of AMD place an individual at highest risk.

Demographics

Among adults ages 55 and older, AMD is the leading cause of vision loss in developed countries. The risk of developing AMD increases with age and is most commonly seen in adults in their sixth and seventh decades. However, AMD has been reported in adults in their fourth decade. In developed countries, approximately one in 2,000 individuals is affected by AMD. By the age of 75, approximately 15% of people have early or mild forms of AMD, and approximately 7% have an advanced form of AMD. Although AMD occurs in both sexes, it is slightly more common in women.

The dry form of AMD is more common than the wet form. More than 85% of people with intermediate and advanced cases of AMD have the dry form. Within the category of advanced AMD, about two-thirds of AMD cases are the wet form. Almost all AMD-related vision loss results from advanced AMD; therefore, the wet, advanced form of AMD leads to significantly more vision loss than the dry form, which has varying stages of development. Individuals who have advanced AMD in one eye are at very high risk of developing it in the other eye.

Signs and symptoms

AMD causes no pain. In some cases, it advances so slowly that affected individuals might not notice much change in their vision. In other cases, the disease progresses quickly and may lead to a loss of vision in both eyes. One of the most common signs of early AMD is drusen, which is yellow deposits under the retina, most common in individuals over age 60. Drusen can be detected during a comprehensive dilated eye exam. Individuals with early AMD have several small drusen to a few medium-sized drusen. At that stage, there are no other symptoms and no vision loss. Individuals with intermediate AMD have many medium-sized drusen to one or more large drusen. The most common symptom at that stage is a blurred area in the central field of vision. Increased light may be necessary for reading and other tasks. Individuals with advanced AMD have drusen along with a degeneration of light-sensitive cells and supporting tissue in the central retinal area. A blurred spot in the central field of vision gets larger and darker over time. There is difficulty reading and recognizing objects from afar. As the AMD progresses, functional vision may be entirely lost in both eyes. AMD may also cause decreased color vision. Vision loss from dry AMD in only one eye may make it harder to notice changes in overall vision, as the other eye compensates.

While the majority of people with AMD maintain their peripheral vision, the severity of symptoms is dependent on the type of AMD. Wet AMD and advanced dry AMD are associated with the most symptoms. Wet AMD may cause straight lines to have a wavy appearance. The degree of change of visual acuity and other symptoms that can be seen by an eye exam increases over time. Individuals with dry AMD usually develop decreased visual acuity very slowly over a period of many years. Detectable changes are small from year to year, and central vision is partially retained. However, individuals with wet AMD usually have symptoms that precipitate quickly and have a greater risk of developing severe central vision loss in as little as a two-month period. Individuals with dry AMD may suddenly develop wet AMD without undergoing progressive stages of dry AMD.

KEY TERMS

Central vision—The ability to see objects located directly in front of the eye; necessary for reading and other activities that require people to focus on objects directly in front of them.

Choroid—A vascular membrane that covers the back of the eye between the retina and the sclera and serves to nourish the retina and absorb scattered light.

Drusen—Fatty deposits that can accumulate underneath the retina and macula and sometimes lead to AMD. Drusen formation can disrupt the photoreceptor cells, which causes central and color vision problems for people with dry AMD.

Exudate—Fluid that accumulates and penetrates the walls of vessels, leaking into the surrounding tissue.

Genetic heterogeneity—The occurrence of the same or similar disease, caused by different genes among different families.

Genome wide association study (GWAS)—A study that examines prevalent genetic variants among many individuals to determine whether the variants are associated with a particular genetic trait, disorder, or single-nucleotide polymorphism.

Macula—A small spot located in the back of the eye that provides central vision and allows people to see colors and fine visual details.

Multifactorial inheritance—A type of inheritance pattern in which many factors, both genetic and environmental, contribute to the cause.

Optic nerve—A bundle of nerve fibers that carries visual messages from the retina in the form of electrical signals to the brain.

Photoreceptors—Specialized cells (rod cells and cone cells) lining the innermost layer of the eye that convert light into electrical messages so that the brain can perceive the environment. Rod cells allow for peripheral and night vision, while cone cells are responsible for perceiving color and for central vision.

Retina—The light-sensitive layer of tissue in the back of the eye that receives and transmits visual signals to the brain through the optic nerve.

Single-nucleotide polymorphism—A single alteration of a nucleotide base (A, T, C, or G) within the DNA sequence of a population of individuals often linked to a genetic disorder or disease.

Diagnosis

A variety of tests are used to diagnose AMD. The visual acuity test measures the smallest letters an individual can read with one eye on a standardized chart at a distance of 20 feet (6 meters). The refraction test involves the same standardized eye chart but requires the patient to focus through a refraction lens to determine the amount of correction needed for optimum visual acuity. The pupillary reflex test examines the ability of the pupil to constrict or dilate in the presence or absence of bright light. The slit lamp examination is also known as biomicroscopy. A high-intensity light source is focused to shine as a slit on the anterior portion of the eye. The eyes are examined with a microscope designed for the eye, called a biomicroscope. The eyes may be temporarily stained with an orange-colored dye called fluorescein to help visualize their structures. Examination of the posterior portion of the eye involves dilating the pupils with specialized eye drops before examination. Retinal photography can then be performed. Fluorescein angiography, or retinal photography, uses fluorescein dye injected into a vein of the arm and a special camera to analyze and photograph the retina, choroid, and associated blood vessels. This examination can be used to visualize the changes in vasculature associated with wet AMD. Tonometry measures the pressure levels inside the eye. Color testing assesses the functioning of the cone cells in recognizing colors. Standardized pictures made up of dots of different colors are arranged in specific patterns and used to determine color recognition. The Amsler grid test uses a printed paper grid to test for decreased central vision, distorted vision, or blind spots.

Although it is known that multiple genes are implicated in AMD, the American Academy of Ophthalmology does not recommend genetic testing for genes associated with AMD. The reason is that even with known specific genetic variants, a person may or may not develop AMD. In addition, there is currently no information available on how to interpret test results as applies to an individual's likelihood of developing AMD. Individuals with AMD are encouraged to monitor changes in their own vision through the use of an Amsler grid.

Treatment and management

There is no universal cure for either type of AMD; however, individuals with wet AMD can prevent further progression of damage with laser photocoagulation therapy. Light rays are focused by a laser to burn off abnormal blood vessels forming beneath the macula, preventing further leakage of blood and fluid. Some normal tissue is also affected. Previously lost vision is not restored with this treatment. Only a small percentage of

wet AMD cases can be treated with laser surgery. It is most effective if the abnormal blood vessels have developed away from the fovea, the central part of the macula. Laser photocoagulation treatments do not prevent future abnormal blood vessels from forming, and they are not effective for dry AMD. In 2000, the FDA approved the use of a light-activated drug called Visudyne (verteporfin), which is injected into the bloodstream via a vein in the arm. It circulates through the body to the eyes, specifically attaching to the abnormal AMD blood vessels present under the macula. When light rays from a non-thermal laser hit these blood vessels, the Visudyne is activated to produce a chemical reaction that destroys the abnormal vessels, causing very little damage to nearby healthy tissues. If the abnormal blood vessels regrow, the procedure is repeated. While this therapy does not cure AMD, it is useful in managing specific problem areas and reducing further vision loss.

Once dry AMD reaches the advanced stage, no form of treatment can prevent vision loss. For this reason, whenever possible, preventive actions before reaching this stage are important. The National Eye Institute's Age-Related Eye Disease Study (AREDS) reported that taking a high-dose antioxidant and zinc supplement significantly reduces the risk of advanced AMD and vision loss. Supplementation is indicated in individuals with intermediate AMD in one or both eyes, or advanced AMD in one but not the other eye. The AREDS reported that supplementation did not keep individuals with early AMD from progressing to an intermediate stage.

Newer medications delay the progression of wet AMD. These medications are in the category of anti-vascular endothelial growth factor (anti-VEGF) drugs. VEGF is a chemical body protein that causes the growth of blood vessels. The three anti-VEGF medications that are used to treat wet AMD as of 2021 include bevacizumab (Avastin), ranibizumab (Lucentis), and aflibercept (Eylea). The ophthalmologist first cleans the eye to decrease the risk for infection and then inserts the drug directly into the eye with a very thin needle. This treatment slows down vision loss and sometimes may improve vision. In 2020, researchers at the National Institutes of Health (NIH) discovered that a protein that deposits mineralized calcium in the teeth may also be the cause of calcium deposits in the back of the eye in individuals with the dry form of AMD. It is hoped that this unique finding will lead to treatments for dry AMD. More recently, in 2021 researcher Mary Elizabeth Hartnett, MD discovered that an oxidized form of cholesterol may lead to AMD. This form of cholesterol is oxysterol 7-ketocholesterol (7KC), and it is also involved in heart disease and cancer. This substance, 7KC, causes scarring in the eyes. It is hoped that this discovery, too, will lead to

QUESTIONS TO ASK YOUR DOCTOR

- How often should I have my vision checked if I am at risk for AMD?
- Are there modifications to my daily routine that could reduce my risk for developing AMD?
- Where can I get an Amsler grid to monitor changes in my vision?
- What is the treatment for advanced AMD, and how successful is it?
- What are the risks associated with treatment, and how were these risks determined?

treatments for dry AMD, which thus far has not been responsive to treatments.

Prognosis

Most individuals with mild dry macular degeneration never develop disabling central vision loss. However, there is no current method of predicting which individuals will progress to an advanced stage of AMD. AMD can cause the loss of central vision only and cannot cause peripheral vision loss. Loss of central vision may interfere with many activities of daily life and significantly impact its quality. An individual with advanced AMD may become functionally blind, so that reading, driving, recognizing faces, and many other common activities become impossible. The prognosis depends on the stage of the disease and type. Mild forms of dry AMD have a better prognosis than advanced dry or wet AMD. As symptoms progress, individuals with AMD become more at risk for psychological distress due to decreasing quality of life and independence. The prognosis improves if low-vision devices and support groups are utilized to improve the quality of life.

Major histocompatibility complex

Definition

In humans, the proteins coded by the genes of the major histocompatibility complex (MHC) include human leukocyte antigens (HLA), as well as other proteins. HLA proteins are present on the surface of most of the body's cells and are important in helping the immune system distinguish "self" from "non-self."

HLA disease associations		
Disease	MHC allele	Approximate relative risk
Ankylosing spondylitis	B27	77–90
Celiac disease	DR3 1 DR7	5–10
Diabetes, Type 1	DR3	5
Diabetes, Type 1	DR4	5–7
Diabetes, Type 1	DR3 1 DR4	20–40
Graves disease	DR3	5
Hemochromatosis	A3	6–20
Lupus	DR3	1–3
Multiple sclerosis	DR2	2–4
Myasthenia gravis	B8	2.5–4
Psoriasis vulgaris	Cw6	8
Rheumatoid arthritis	DR4	3–6

The relative risks indicated in this table refer to the increased chance of a patient with an MCH allele to develop a disorder as compared to an individual without one. For example, a patient with DR4 is three to six times more likely to have rheumatoid arthritis and five to seven times more likely to develop type 1 diabetes than an individual without the DR4 allele.

Gale (Memorisz/Shutterstock)

Description

The function and importance of MHC is best understood in the context of a basic understanding of the function of the immune system. The immune system is responsible for distinguishing "self" from "non-self," primarily with the goal of eliminating foreign organisms and other invaders that can result in disease. There are several levels of defense characterized by the various stages and types of immune response.

Natural immunity

When a foreign organism enters the body, it is encountered by the components of the body's natural immunity. Natural immunity is the non-specific first line of defense carried out by phagocytes, natural killer cells (NK cells), and components of the complement system. Phagocytes are specialized white blood cells capable of engulfing and killing an organism. NK cells are also specialized white blood cells that respond to cancer cells and certain viral infections. The complement system is a group of proteins called the class III MHC that attack antigens. Antigens consist of any molecule capable of triggering an immune response. Although this list is not exhaustive, antigens can be derived from toxins, protein, carbohydrates, DNA, or other molecules from viruses, bacteria, cellular parasites, or cancer cells.

Acquired immunity

The natural immune response holds an infection at bay as the next line of defense mobilizes through acquired, or specific, immunity. This specialized type of immunity

KEY TERMS

Acquired immunity—Also called specific immunity, refers to immune reaction mediated by B-cells and/or T-cells. Includes humoral and cellular immunity.

Allele—One of two or more alternate forms of a gene.

Antibody—A protein produced by the mature B cells of the immune system that attach to invading microorganisms and target them for destruction by other immune system cells.

Antigen—A substance or organism that is foreign to the body and stimulates a response from the immune system.

Antigen presenting cell—Cells that are able to present foreign antigen in conjunction with MHC proteins to the immune system.

Autoimmune—Referring to an immune reaction erroneously directed toward “self” tissues.

B-cell—Specialized type of white blood cell that is capable of secreting infection-fighting antibodies.

Base pairs—Building blocks of DNA, the chemical that genes are made of.

Beta-2 microglobulin—A component protein of class I MHC.

Bone marrow—A spongy tissue located in the hollow centers of certain bones, such as the skull and hip bones. Bone marrow is the site of blood cell generation.

Cellular immunity—A type of acquired immunity mediated by killer T-cells; important in fighting “hidden” infections, such as those caused by cellular parasites and some viruses.

Class I MHC—Includes *HLA-A*, *HLA-B*, and *HLA-C*. Important in cellular immunity.

Class II MHC—*HLA-DP*, *HLA-DQ*, and *HLA-DR*. Important in humoral immunity.

Class III MHC—Includes the complement system.

Co-dominant—Describes the state when two alleles of the same gene are both expressed when inherited together.

Complement system—Class III MHC (major histocompatibility complex) proteins capable of destroying invading organisms directly via natural immunity, as well as indirectly through an interaction with other components of the immune system.

Cytokines—Proteins released by helper T-cells that stimulate and support immune responses mediated by B-cells and killer T-cells.

Graft-versus-host disease—In bone marrow transplantation, the complication that occurs when the donor’s cells attack the recipient’s tissues, in part due to non-identical donor-recipient HLA types.

Haplotype—A set of alleles that are inherited together as a unit on a single chromosome because of their close proximity.

Helper T-cell—Specialized white blood cell that assists in humoral and cellular immunity.

Human leukocyte antigens (HLA)—Proteins that help the immune system function, in part by helping it to distinguish “self” from “non-self.”

Humoral immunity—A type of acquired immunity mediated by B-cells and their secreted antibodies; important in fighting bacterial and some viral infections.

Major histocompatibility complex (MHC)—Includes HLA, as well as other components of the immune system. Helps the immune system function, in part by helping it to distinguish “self” from “non-self.”

Memory cells—B-cells whose antibodies recognized antigens from a previous infection; able to mount a quick, efficient response upon a second infection by the same organism.

Natural immunity—First line immune response that is non-specific. Includes action of phagocytes, natural killer cells, and complement cells.

Natural killer cells—Specialized white blood cells involved in natural immunity. Can kill some viruses and cancer cells.

Phagocyte—White blood cells capable of engulfing and destroying foreign antigen or organisms in the fluids of the body.

Plasma cells—Antibody-secreting B-cells.

Polymorphic—Describes a gene for which there exist multiple forms, or alleles.

Thymus gland—An endocrine gland located in the front of the neck that houses and transports T-cells, which help to fight infection.

is usually needed to eliminate an infection and is dependent on the role of the proteins of the major histocompatibility complex. There are two types of acquired immunity. Humoral immunity is important in

fighting infections outside the body’s cells, such as those caused by bacteria and certain viruses. Other types of viruses and parasites that invade the cells are better fought by cellular immunity. The major players in acquired

immunity are the antigen-presenting cells (APCs), B-cells and their secreted antibodies, and the T-cells.

Humoral immunity

In humoral immunity, antigen-presenting cells, including some B-cells, engulf and break down foreign organisms. Antigens from these foreign organisms are then brought to the outside surface of the antigen-presenting cells and presented in conjunction with class II MHC proteins. The helper T-cells recognize the antigen presented in this way and release cytokines, proteins that signal B-cells to take further action. B-cells are specialized white blood cells that mature in the bone marrow. Through the process of maturation, each B-cell develops the ability to recognize and respond to a specific antigen. Helper T-cells aid in stimulating the few B-cells that can recognize a particular foreign antigen. B-cells that are stimulated in this way develop into plasma cells, which secrete antibodies specific to the recognized antigen. Antibodies are proteins that are present in the circulation, as well as being bound to the surface of B-cells. They can destroy the foreign organism from which the antigen came. Destruction occurs either directly, or by “tagging” the organism, which is then more easily recognized and targeted by phagocytes and complement proteins. Some of the stimulated B-cells go on to become memory cells, which are able to mount an even faster response if the antigen is encountered a second time.

Cellular immunity

Another type of acquired immunity involves killer T-cells and is termed cellular immunity. T-cells go through a process of maturation in the organ called the thymus, in which T-cells that recognize “self” antigens are eliminated. Each remaining T-cell has the ability to recognize a single, specific, “non-self” antigen that the body may encounter. Although the names are similar, killer T-cells are unlike the non-specific NK cells in that they are specific in their action. Some viruses and parasites quickly invade the body’s cells, where they are “hidden” from antibodies. Small pieces of proteins from these invading viruses or parasites are presented on the surface of infected cells in conjunction with class I MHC proteins, which are present on the surface of nearly all of the body’s cells. Killer T-cells can recognize antigen bound to class I MHC in this way, and they are prompted to release chemicals that act directly to kill the infected cell. There is also a role for helper T-cells and antigen-presenting cells in cellular immunity. Helper T-cells release cytokines, as in the humoral response, and the cytokines stimulate killer T-cells to multiply. Antigen-presenting cells carry foreign antigen to places in the body where additional killer T-cells can be alerted and recruited.

The major histocompatibility complex clearly performs an important role in the functioning of the immune system. Related to this role in disease immunity, MHC is also important in organ and tissue transplantation, as well as playing a role in susceptibility to certain diseases. HLA typing can provide important information in parentage, forensic, and anthropologic studies.

Genetic profile

Present on chromosome 6, the major histocompatibility complex consists of more than 70 genes, classified into class I, II, and III *MHC*. There are multiple alleles, or forms, of each *HLA* gene. These alleles are expressed as proteins on the surface of various cells in a co-dominant manner. This diversity is important in maintaining an effective system of specific immunity. Altogether, the *MHC* genes span a region that is four million base pairs in length. Although this is a large region, 99% of the time these closely linked genes are transmitted to the next generation as a unit of MHC alleles on each chromosome 6. This unit is called a haplotype.

Class I

Class I *MHC* genes include *HLA-A*, *HLA-B*, and *HLA-C*. Class I *MHC* genes are expressed on the surface of almost all cells. They are important for displaying antigen from viruses or parasites to killer T-cells in cellular immunity. Class I *MHC* is particularly important in organ and tissue rejection following transplantation. In addition to the portion of class I *MHC* coded by the genes on chromosome 6, each class I MHC protein also contains a small, non-variable protein component called beta-2 microglobulin coded by a gene on chromosome 15. Class I *HLA* genes are highly polymorphic, meaning there are multiple forms, or alleles, of each gene. There are at least 57 *HLA-A* alleles, 111 *HLA-B* alleles, and 34 *HLA-C* alleles.

Class II

Class II *MHC* genes include *HLA-DP*, *HLA-DQ*, and *HLA-DR*. Class II *MHC* genes are particularly important in humoral immunity. They present foreign antigens to helper T-cells, which stimulate B-cells to elicit an antibody response. Class II *MHC* is only present on antigen-presenting cells, including phagocytes and B-cells. Like class I *MHC*, there are hundreds of alleles that make up the class II *HLA* gene pool.

Class III

Class III *MHC* genes include the complement system (i.e., C2, C4a, C4b, Bf). Complement proteins help to

activate and maintain the inflammatory process of an immune response.

Demographics

There is significant variability of the frequencies of HLA alleles among ethnic groups. This is reflected in anthropologic studies attempting to use HLA types to determine patterns of migration and evolutionary relationships in peoples of various ethnicities. Ethnic variation is also reflected in studies of HLA-associated diseases. Generally speaking, populations that have been subject to significant patterns of migration and assimilation with other populations tend to have a more diverse HLA gene pool. For example, it is unlikely that two unrelated individuals of African ancestry would have matched HLA types. Conversely, populations that have been isolated due to geography, cultural practices, and other historical influences may display a less diverse pool of HLA types, making it more likely for two unrelated individuals to be HLA-matched.

Testing

Organ and tissue transplantation

There is a role for HLA typing of individuals in various settings. Commonly, HLA typing is used to establish whether an organ or tissue donor is appropriately matched to the recipient for key HLA types, so as not to elicit a rejection reaction in which the recipient's immune system attacks the donor tissue. In the special case of bone marrow transplantation, the risk is for graft-versus-host disease (GVHD), as opposed to tissue rejection. Because the bone marrow contains the cells of the immune system, the recipient effectively receives the donor's immune system. If the donor immune system recognizes the recipient's tissues as foreign, it may begin to attack, causing the inflammation and other complications of GVHD. As advances occur in transplantation medicine, HLA typing for transplantation occurs with increasing frequency and in various settings.

Disease susceptibility

There is an established relationship between the inheritance of certain HLA types and susceptibility to specific diseases. Most commonly, these are diseases that are thought to be autoimmune in nature. Autoimmune diseases are those characterized by inflammatory reactions that occur as a result of the immune system mistakenly attacking "self" tissues. The basis of the HLA association is not well understood, although there are some hypotheses. Most autoimmune diseases are characterized by the expression of class II MHC on cells of the body that do not normally express these proteins. This

may confuse the killer T-cells, which respond inappropriately by attacking these cells. Molecular mimicry is another hypothesis. Certain HLA types may look like antigen from foreign organisms. If an individual is infected by such a foreign virus or bacteria, the immune system mounts a response against the invader. However, there may be a cross-reaction with cells displaying the HLA type that is mistaken for a foreign antigen. Whatever the underlying mechanism, certain HLA types are known factors that increase the relative risk for developing specific autoimmune diseases. For example, individuals who carry the HLA B-27 allele have a relative risk of 77–90 for developing ankylosing spondylitis—meaning such an individual has a 77–90-fold chance of developing this form of spinal and pelvic arthritis, as compared to someone in the general population.

In addition to autoimmune disease, HLA type less commonly plays a role in susceptibility to other diseases, including cancer, certain infectious diseases, and metabolic diseases. Conversely, some HLA types confer a protective advantage for certain types of infectious disease. In addition, there are rare immune deficiency diseases that result from inherited mutations of the genes of components of the major histocompatibility complex.

Parentage

Among other tests, HLA typing can sometimes be used to determine parentage, most commonly paternity, of a child. This type of testing is not generally done for medical reasons, but rather for social or legal reasons.

Forensics

HLA typing can provide valuable DNA-based evidence contributing to the determination of identity in criminal cases. This technology has been used in domestic criminal trials. Additionally, it is a technology that has been applied internationally in the human-rights arena. For example, HLA typing had an application in Argentina following a military dictatorship that ended in 1983. The period under the dictatorship was marked by the murder and disappearance of thousands who were known or suspected of opposing the regime's practices. Children of those who disappeared were often "adopted" by military officials and others. HLA typing was one tool used to determine non-parentage and return children to their biological families.

Anthropologic studies

HLA typing has proved to be an invaluable tool in the study of the evolutionary origins of human populations. This information, in turn, contributes to an understanding

of cultural and linguistic relationships and practices among and within various ethnic groups.

Male infertility

Definition

Male infertility is defined as the inability of a male to impregnate a female after at least one year of trying to conceive a child.

Description

There are many causes of male infertility. The most common causes are physical problems with the functioning of the testicles, such as undescended testicles. Hormone imbalances or blockages in the reproductive organs, such as in the ducts that carry the sperm (the vasa deferentia), are also common causes of male infertility. About 10%–15% of infertile men have a complete lack of sperm. About 40% of men with fertility problems have an enlarged vein in the testicle called a varicocele, which is the most common cause of low sperm production. Illnesses—such as a history of high fevers, mumps, or other infections—injuries, chronic health problems such as celiac disease, certain medications or surgeries, and lifestyle or environmental factors can also contribute to

Light micrograph of normal and atypical sperm. (GJLP, CNRI/Science Source)

male infertility. Other causes include problems with sexual intercourse or ejaculation and immune-system antibodies that mistakenly attack sperm. Finally, several genetic conditions result in male infertility. In about 50% of cases of male infertility, the cause cannot be determined.

Genetic causes of male infertility include:

- Y chromosome infertility—deletions in the Y chromosome that affect sperm production
- azoospermia—the complete absence of sperm
- teratozoospermia—abnormal sperm
- cystic fibrosis (CF)
- sensorineural deafness with male infertility
- X-linked congenital adrenal hypoplasia and Kallmann syndrome
- Klinefelter syndrome
- 48,XXYY syndrome
- Kartagener syndrome (primary ciliary dyskinesia with situs inversus totalis)

Genetic profile

Abnormal sperm production

Y chromosome infertility is a condition in which the male produces no sperm cells (azoospermia), fewer than the usual number of sperm (oligospermia), or sperm cells that are abnormally shaped or that do not swim properly. Most cases of Y chromosome infertility are caused by deletions in the A, B, or C regions of the azoospermia factor (AZF) region of the Y chromosome, which contains genes that provide instructions for producing proteins involved in sperm-cell development. Rarely, Y chromosome infertility is caused by mutations in the *USP9Y* gene located in AZF region A, which produces a protein called ubiquitin-specific protease 9. Some men with Y chromosome infertility that results in mild-to-moderate

oligospermia may eventually father a child naturally. Assisted reproductive technologies (ART) may help other affected men, since most men with Y chromosome infertility have some sperm cells in their testes that can be extracted for ART. The most severely affected men do not have any mature sperm cells in the testes. This form of Y chromosome infertility is called Sertoli-cell-only syndrome. Because men with AZF deletions are infertile, they do not normally pass on the genetic defect; thus, Y chromosome infertility is usually caused by new deletions in the Y chromosome in men without a family history of the disorder. However, when such men do reproduce, either naturally or by ART, they pass the defect on to all of their male offspring.

With azoospermia, no sperm are detectable in the seminal fluid. Non-obstructive azoospermia, in which the lack of sperm is not due to a physical obstruction, can be caused by mutations in the *SYKP3*, *KLHL10*, *AURKC*, or *SPATA16* genes, which are located in the AZF region of the Y chromosome and on autosomes (chromosomes other than the X and Y sex chromosomes). Mutations in the *TEX11* (*testis-expressed 11*) gene, on the long arm (q) of the X chromosome at Xq13.2, have been identified as also causing non-obstructive azoospermia. *TEX11* is required for sperm maturation.

Mutations in several different genes have been identified as causing teratozoospermia—a condition in which at least 85% of sperm are abnormal. The heads of normal sperm are oval-shaped with a cap called an acrosome containing enzymes that break down the outer membrane of the egg cell. Normal sperm also have one flagellum that enables them to swim to the egg. If all of the sperm have the same abnormal appearance, the condition is called monomorphic teratozoospermia. Mutations that cause monomorphic teratozoospermia are autosomal recessive, which means that two mutated genes are required for the production of the abnormal sperm, and these genes are not located on the X or Y sex chromosomes. Females are not affected by these mutations since they do not produce sperm. There are two types of monomorphic teratozoospermia: macrozoospermia and globozoospermia, which together account for less than 1% of cases of male infertility. In cases of monomorphic teratozoospermia, intracytoplasmic sperm injection (ICSI), a type of ART in which the sperm is injected directly into the egg in the laboratory prior to implantation in the woman's uterus, is generally unsuccessful because the sperm are abnormal.

In macrozoospermia, also called macrocephalic sperm head syndrome, the sperm heads are abnormally large and misshapen and, instead of one flagellum, the sperm have multiple (usually four) flagella. Most cases

KEY TERMS

Acrosome—The cap at the top of the sperm head that releases egg-penetrating enzymes.

Assisted reproductive technology (ART)—Infertility treatments such as in vitro fertilization and intracytoplasmic sperm injection.

Autosomal recessive—A pattern of genetic inheritance in which two abnormal genes are required to express a disorder.

Azoospermia—The absence of sperm in the seminal fluid.

Azoospermia factor (AZF)—A region of the Y chromosome containing genes that are important for male fertility.

Cystic fibrosis (CF)—An inherited genetic disorder that affects many body systems and is caused by mutations in the CFTR gene that can also cause congenital bilateral absence of vas deferens and male infertility.

Globozoospermia—A genetic condition in which sperm have round heads and lack acrosomes, among other defects, resulting in male infertility.

Intracytoplasmic sperm injection (ICSI)—In vitro fertilization in which sperm is injected directly into the cytoplasm of the egg.

Klinefelter syndrome—A genetic disorder in which cells have two X chromosomes in addition to a Y chromosome, resulting in male infertility and possibly other problems; an XXY male.

Macrozoospermia—Macrocephalic sperm head syndrome; male infertility due to sperm with abnormally large heads and multiple (usually four) flagella; caused by mutations in the *AURKC* gene.

Nondisjunction—Failure of homologous chromosomes or sister chromatids to separate during meiosis or mitosis, resulting in cells with an abnormal complement of chromosomes.

Oligospermia—Production of fewer than normal amounts of sperm.

Seminal fluid—Fluid from the prostate and other sex glands that transports sperm.

Teratozoospermia—A condition in which at least 85% of sperm are abnormal; caused by mutations in several different genes.

Testicles—Two oval organs that produce sperm and are enclosed in the scrotum.

Vas deferens, pl. vasa deferentia—The tube that transports sperm from the testicle to the ejaculatory tube.

of macrozoospermia have been identified as resulting from at least four different mutations in both *AURKC* genes (homozygous mutations) that encode the enzyme aurora kinase C. This gene is essential for spermatogenesis—the reduction in chromosomes during meiosis that distributes only one chromosome from each chromosome pair to each sperm cell. *AURKC* mutations result in a failure of meiosis, so that the sperm have two or four sets of chromosomes instead of one. The *AURKC* mutations that cause macrozoospermia result in a non-functional enzyme or an enzyme that breaks down quickly in the testes, thereby blocking cell division during spermatogenesis. The extra chromosomes increase the size of the sperm head. If such an abnormal sperm cell does fertilize an egg, the embryo does not develop, or the pregnancy ends in miscarriage.

In globozoospermia, all of the sperm have abnormally round heads and other defects, including the lack of an acrosome and a defective nuclear membrane. About 70% of men with globozoospermia have mutations in the *DPY19L2* (*Dpy-19 Like 2*) gene, which produces a protein that is involved in elongating the sperm head and forming the acrosome during sperm-cell maturation. Globozoospermia can also be caused by mutations in the *SPATA16* gene (*spermatogenesis-associated 16*) and in the *PICK1* gene.

CATSPER1-related nonsyndromic male infertility is a condition in which fewer sperm are produced, or they are abnormally shaped, and the sperm have decreased motility (movement). It is called nonsyndromic because it does not cause any other symptoms. The *CATSPER1* gene produces a protein in flagella that is required for propelling the sperm forward and pushing them through the outside membrane of the egg during fertilization. Mutations in *CATSPER1* produce a protein that is abnormal, nonfunctional, or rapidly broken down, causing the sperm tails to move slowly. *CATSPER1* mutations are inherited in an autosomal recessive pattern. Abnormalities in sperm flagella can also be caused by mutations in the *DNAH1* gene that encodes heavy chain 1 of the axonemal dynein protein.

Syndromes

Congenital bilateral absence of vas deferens occurs when the two vasa deferentia fail to develop properly. This condition accounts for 1%–2% of all male infertilities. Males with this condition can only conceive children via ART. The condition may occur alone or in conjunction with mutations in the *CFTR* gene that causes CF. Although more than half of men with congenital bilateral absence of vas deferens have mutations in the *CFTR* gene, many of them do not have other symptoms of CF or have only mild respiratory or digestive problems. The *CFTR*

gene produces a protein that forms a channel for transporting chloride ions in and out of cells, which helps control water movement in tissues and is necessary for producing thin, flowing mucus for lubricating and protecting the airways, digestive system, and reproductive system, as well as other organs and tissues. *CFTR* mutations result in the production of thick, sticky mucus that clogs the vasa deferentia as they form in the fetus, resulting in their destruction before birth. Mutations in *CFTR* that cause CF are autosomal recessive. However, a second mutation in the *CFTR* gene, called R117H, is a dominant mutation. Depending on other characteristics of the *CFTR* gene, R117H mutations, as well as another mutation in the *CFTR* gene, can cause congenital bilateral absence of vas deferens even if the second *CFTR* gene is normal, and the male does not have CF.

Male infertility with sensorineural deafness is an autosomal recessive condition caused by deletions in the long arm of chromosome 15, resulting in the loss of several genes. In addition to hearing loss due to abnormalities in the inner ear, males produce sperm with decreased motility. Deletion of the *STRC* gene causes hearing loss, and deletion of the *CATSPER2* gene in the same region of the chromosome results in male infertility.

Congenital X-linked adrenal hypoplasia is caused by mutations in the *NROB1* gene that produces a protein called DAX1, which is important for the development of hormone-producing and hormone-secreting glands, including the adrenal glands, hypothalamus and pituitary in the brain, and the testes in males. Mutations in *NROB1* may delete the entire gene or produce an inactive DAX1 protein. This causes adrenal insufficiency and hypogonadotropic hypogonadism, in which hormone production is disrupted. The lack of male sex hormones leads to underdevelopment of the reproductive tissues and infertility. These mutations primarily affect males, since females have a second X chromosome with a normal gene that can compensate for the mutation.

Kallmann syndrome also causes hypogonadotropic hypogonadism, delayed puberty, anosmia (an inability to smell), and male infertility if untreated. Kallmann syndrome can be caused by mutations in several different genes. Most cases are sporadic, meaning that they are caused by new gene mutations rather than mutations inherited from a parent. However, some cases are inherited in an autosomal dominant, autosomal recessive, or X-linked recessive pattern.

Chromosome abnormalities

Male infertility is the most common symptom of Klinefelter syndrome, in which males have two X chromosomes and one Y chromosome instead of one X

QUESTIONS TO ASK YOUR DOCTOR

- Is the man or woman more likely to be the cause of infertility?
- How is male infertility diagnosed?
- Is genetic testing available for male infertility?
- Can assisted reproductive technologies overcome male infertility?

chromosome and one Y chromosome. This results in abnormal development of the male reproductive organs. The extra X chromosome results from an error during egg or sperm cell formation. Although testosterone therapy can improve other symptoms of Klinefelter syndrome, most men remain infertile.

48,XXYY syndrome, in which males have two X chromosomes and two Y chromosomes instead of one of each, causes a variety of medical and behavioral problems including a disruption of sexual development. The small testes do not produce sufficient testosterone (the male sex hormone) to promote puberty, and the abnormal functioning of the testes causes infertility. Although many genes are present only on the X or Y chromosome alone, genes in the pseudoautosomal regions are present on both X and Y chromosomes. Thus, males with 48,XXYY syndrome have extra copies of these genes, which contribute to the signs and symptoms of the syndrome. 48,XXYY is not inherited; rather, it occurs through an error in cell division called nondisjunction that leaves a sperm cell with extra chromosomes. In a small number of cases, the nondisjunction occurs soon after fertilization of a normal egg cell (with one X chromosome) by a normal sperm (with one Y chromosome).

Demographics

Male infertility affects more than 20 million men worldwide. About one-third of all infertilities are caused by male infertility, one-third by female infertility, and one-third by infertility in both the male and female or by unknown factors. However, only a fraction of male infertilities have genetic causes.

- Y chromosome infertility affects 1 man in 2,000–3,000 worldwide and accounts for 5%–10% of azoospermias and severe oligospermias.
- Macrozoospermia affects an estimated 1 in 10,000 males in North Africa. Its prevalence outside of North Africa is unknown.

- Globozoospermia is estimated to affect 1 in 65,000 males, but is most common in North Africa where it accounts for about 1 in 100 cases of male infertility.
- Congenital X-linked adrenal hypoplasia affects 1 in 12,500 newborns.
- Klinefelter syndrome occurs in about 1 in every 500–1,000 male newborns.
- 48,XXYY affects an estimated 1 in 18,000–50,000 males.

Signs and symptoms

Other than the inability to conceive a child, symptoms of male infertility depend on the underlying cause, but may include the following:

- low sperm count (fewer than 15 million sperm per milliliter of semen or fewer than 39 million per ejaculate)
- problems with sexual function
- pain, swelling, or lumps in the testicle area
- decreased facial or body hair

Diagnosis

Diagnosis of male infertility may include the following:

- a medical history of inherited disorders, sexual development, chronic disorders, illnesses, injuries, or surgeries
- examination of the genitals
- semen analysis, including sperm counts and abnormalities in sperm shape or motility
- sperm function tests for survival and attachment to and penetration of the egg
- genetic testing for chromosome abnormalities and/or gene mutations
- ultrasound examination
- hormone testing
- post-ejaculation urinalysis for sperm traveling backward into the bladder
- testicular biopsy
- new genetic tests for RNA elements in sperm that have been identified as essential for male fertility, including RNAs that are essential for sperm development, motility, energy production, fertilization, and embryo formation

Treatment and management

Treatment depends on the cause of the infertility. If healthy sperm are present in the testicles, as with infertility due to *CFTR* mutations, they may be retrieved from the testicles or epididymis (the ducts in which sperm mature before entering the vas deferens) and used for ICSI or in vitro fertilization.

Prognosis

Prognosis depends on the cause of the male infertility. Biological fatherhood is not possible if no healthy, mature sperm are produced.

Malignant hyperthermia

Definition

Malignant hyperthermia (MH) is a condition that causes a number of physical changes to occur among genetically susceptible individuals when they are exposed to a particular muscle relaxant or certain types of medications used for anesthesia. The changes may include increased rate of breathing, increased heart rate, muscle

stiffness, and significantly increased body temperature (i.e., hyperthermia). Although MH can usually be treated successfully, it sometimes leads to long-term physical illness or death. Research has identified a number of genetic regions that may be linked to an increased MH susceptibility.

Description

Unusual response to anesthesia was first reported in a medical journal in the early 1960s, when physicians described a young man in need of urgent surgery for a serious injury. He was very nervous about exposure to anesthesia, since he had ten close relatives who died during or just after surgeries that required anesthesia. The patient himself became very ill and developed a high temperature after he was given anesthesia. During the next decade, more cases of similar reactions to anesthesia were reported, and specialists began using the term "malignant hyperthermia" to describe the newly recognized condition. The word "hyperthermia" was used because people with this condition often develop a very high body temperature rapidly. The word "malignant" referred to the fact that the majority (70%–80%) of affected individuals died. The high death rate in the 1960s occurred because the underlying cause of the condition was not understood, nor was there any known treatment (other than trying to cool the person's body with ice).

Increased awareness of malignant hyperthermia and scientific research during the following decades improved medical professionals' knowledge about what causes the condition, how it affects people, and how it should be treated. MH can be thought of as a chain reaction that is triggered when a person with MH susceptibility is exposed to specific drugs commonly used for anesthesia and muscle relaxation.

Triggering drugs that may lead to malignant hyperthermia include the following:

- halothane
- enflurane
- isoflurane
- sevoflurane
- desflurane
- methoxyflurane
- ether
- succinylcholine

Once an MH-susceptible person is exposed to one or more of these anesthesia drugs, he or she can present with a variety of signs. One of the first clues that a person is susceptible to MH is often seen when the person is given a muscle relaxant called succinyl choline. This drug generally causes some stiffness in the masseter (jaw) muscles

in most people. However, individuals with MH susceptibility can develop a much more severe form of jaw stiffness called masseter spasm when they receive this drug. They may develop muscle stiffness in other parts of their bodies as well. When exposed to any of the trigger drugs (inhalants for anesthesia), people with MH susceptibility can develop an increased rate of metabolism in the cells of the body, resulting in rapid breathing, rapid heartbeat, high body temperature (over 110°F), muscle stiffness, and muscle breakdown. If these signs are not recognized, treated, or able to be controlled, brain damage or death can occur due to internal bleeding, heart failure, or failure of other organs.

The series of events that occur after exposure to trigger drugs is activated by an abnormally high amount of calcium inside muscle cells. This is due to changes in the chemical reactions that control muscle contraction and the production of energy. Calcium is normally stored in an area called the sarcoplasmic reticulum, which is a system of tiny tubes located inside muscle cells. This system of tubes allows muscles to contract (by releasing calcium) and to relax (by storing calcium) in muscle cells. Calcium also plays an important role in the production of energy inside cells (i.e., metabolism). There are at least three important proteins located in (or nearby) the sarcoplasmic reticulum that control how much calcium is released into muscle cells and thus help muscles contract. One of these proteins is a calcium release channel protein that has been named the ryanodine receptor protein, or RYR. This protein (as well as the gene that tells the body how to make it) has been an important area of research. For some reason, when people with MH susceptibility are exposed to a trigger drug, they can develop very high levels of calcium in their muscle cells. The trigger drugs presumably stimulate the proteins that control the release of calcium, causing them to create very high levels of calcium in muscle cells. This abnormally high calcium level then leads to increased metabolism, muscle stiffness, and the other symptoms of MH.

The amount of time that passes between the exposure to trigger drugs and the appearance of the first symptoms of MH varies between different people. Symptoms begin within ten minutes for some individuals, although several hours may pass before symptoms appear in others. This means that some people do not show signs of MH until they have left the operating room and are recovering from surgery. In addition, some individuals who inherit MH susceptibility may be exposed to trigger drugs numerous times during multiple surgeries without any complications. However, they still have an increased risk to develop an MH episode during future exposures. This means that people who have an increased risk for MH susceptibility due to their family history cannot presume

that they are not at risk simply because they previously had successful surgeries. Although MH was frequently a fatal condition in the past, a drug called dantrolene sodium, which greatly decreased the rate of both death and disability, became available in 1979.

Genetic profile

Susceptibility to MH is generally considered to be inherited as an autosomal dominant trait. “Autosomal” means that males and females are equally likely to be affected. “Dominant” refers to a specific type of inheritance in which only one copy of a person’s gene pair needs to be changed in order for the susceptibility to be present. In this situation, an individual susceptible to MH receives a changed copy of the same gene from one parent (who is also susceptible to MH). This means that a person with MH susceptibility has one copy of the changed gene and one copy of the gene that works well. The chance that a parent with MH susceptibility will have a child who is also susceptible is 50% for each pregnancy. The same parent would also have a 50% chance to have a non-susceptible child with each pregnancy.

It is not unusual for people to not know they inherited a genetic change that causes MH susceptibility. This is because they typically do not show symptoms unless they are exposed to a specific muscle relaxant or certain anesthetics, which may not be needed by every person during his or her lifetime. In addition, people who inherit MH susceptibility do not always develop a reaction to trigger drugs, which means their susceptibility may not be recognized even if they do have one or more surgeries. Once MH susceptibility is diagnosed in an individual, however, it is important for his or her family members to know that they too have a risk for MH susceptibility, since it is a dominant condition. This means that individuals with a family member who has MH susceptibility should tell their doctor about their family history. Since MH may go unrecognized, it is important that anyone who has had a close relative die from anesthesia notify the anesthesiologist before any type of surgery is planned. People with a family history of MH susceptibility may choose to meet with a genetic counselor to discuss the significance of their family history as well. In addition, relatives of an affected person may consider having a test to see if they also inherited MH susceptibility.

Although there are many people who have the same symptoms of MH when exposed to trigger drugs, genetic research has shown that there are probably many genes, located on different chromosomes, that can all lead to MH susceptibility. This indicates that there is genetic heterogeneity among different families with MH susceptibility, meaning that different genes can lead to the same or

similar disease among different families. Researchers identified six different types of MH susceptibility. Although specific genes have been discovered for some of these types, others have been linked only to specific chromosomal regions.

Genetic classification of malignant hyperthermia includes the following:

- **MHS1**—Located on chromosome 19q13.1. Specific gene called *RYR1*. Gene creates the RYR protein.
- **MHS2**—Located on chromosome 17q11.2-24. Suspected gene called *SCN4A*.
- **MHS3**—Located on chromosome 7q21-22. Suspected gene called *CACNA2D1*. Gene creates part of the DHPR protein called the alpha 2/delta subunit.
- **MHS4**—Located on chromosome 3q13.1. Specific gene and protein unknown.
- **MHS5**—Located on chromosome 1q32. Specific gene called *CACNA1S*. Gene creates part of the DHPR protein called the alpha 1 subunit.
- **MHS6**—Located on chromosome 5p. Specific gene and protein unknown.

Over half of all families with MH susceptibility are believed to have MHS1 (i.e., have changes in the *RYR1* gene), while the rest have MHS2, MHS3, MHS4, MHS5, or MHS6. Only about 20% of all families tested have specific genetic changes identified in the *RYR1* gene. This is because there are many different types of genetic changes in the gene that can all lead to MH susceptibility, and many families have changes that are unique. As a result, genetic testing of the *RYR1* gene is complicated, time consuming, and often cannot locate all possible genetic changes. In addition, genetic testing for families may become more complex as knowledge about MH grows. Although MH susceptibility has typically been described as an autosomal dominant trait caused by a single gene that is passed from one generation to the next, MH susceptibility may actually depend upon various genetic changes that occur in more than one gene. Further research may clarify this issue.

While specific genes have been identified for some of the MH susceptibility types (i.e., *RYR1* and *DHPR* alpha 1 subunit), not all changes in these genes lead specifically to MH susceptibility. For example, although at least 20 different genetic changes that can lead to MH susceptibility have been identified in the *RYR1* gene, some people who have certain types of these changes actually have a different genetic condition called central core disease (CCD) that affects the muscles. Infants with this autosomal dominant condition typically have very poor muscle tone (i.e., muscle tension) as well as an

KEY TERMS

Anesthesia—Lack of normal sensation (especially to pain) brought on by medications just prior to surgery or other medical procedures.

Genetic heterogeneity—The occurrence of the same or similar disease, caused by different genes among different families.

Hyperthermia—Body temperature that is much higher than normal (i.e., higher than 98.6°F).

Masseter spasm—Stiffening of the jaw muscles. Often one of the first symptoms of malignant hyperthermia susceptibility that occurs after exposure to a trigger drug.

Metabolism—The total combination of all of the chemical processes that occur within cells and tissues of a living body.

Sarcoplasmic reticulum—A system of tiny tubes located inside muscle cells that allow muscles to contract and relax by alternatively releasing and storing calcium.

Trigger drugs—Specific drugs used for muscle relaxation and anesthesia that can trigger an episode of malignant hyperthermia in a susceptible person. The trigger drugs include halothane, enflurane, isoflurane, sevoflurane, desflurane, methoxyflurane, ether, and succinylcholine.

increased susceptibility to MH. Among families who have CCD, there are some individuals who do not have the typical muscle changes but have MH susceptibility instead. Future research may help scientists understand why the same genetic change in the *RYR1* gene can cause different symptoms among people belonging to the same family.

Demographics

The exact number of individuals who are born with a genetic change that causes MH susceptibility is not known. Until genetic research and genetic testing improve, this number will likely remain unclear. It is estimated that internationally 1 in 50,000 people who are exposed to anesthesia develop an MH reaction. Among children, it is estimated that 1 in 5,000 to 1 in 15,000 develop MH symptoms when exposed to anesthesia. MH has been seen in many countries, although there are some geographic areas in which it occurs more often in the local populations, including parts of Wisconsin, North Carolina, Austria, and Quebec.

Signs and symptoms

Although the specific symptoms of malignant hyperthermia can vary, the most common findings include the following:

- stiffness/spasms of jaw muscles and other muscles
- rapid breathing, causing decreased oxygen and increased carbon dioxide in the blood
- rapid or irregular heartbeat
- high body temperature (over 110°F)
- muscle breakdown (may cause dark or cola-colored urine)
- internal bleeding, kidney failure, brain damage, or death (if not treated successfully)

Diagnosis

The diagnosis of MH susceptibility can be made before or during a reaction to a triggering drug. Ideally, the diagnosis is made before a susceptible individual is exposed and/or develops a reaction. This is possible for people who learn they have an increased chance for MH because they have a relative with MH susceptibility. Testing these individuals requires a surgical procedure called a muscle biopsy, in which a piece of muscle tissue is removed from the body (usually from the thigh). Safe (i.e., non-triggering) anesthetics are used during the procedure. The muscle is taken to a laboratory and is exposed to halothane (a triggering anesthetic) and caffeine, both of which cause any muscle tissue to contract, or tighten. Thus, the test is called the caffeine halothane contracture test (CHCT). Muscle tissue taken from individuals with MH susceptibility is more sensitive to caffeine and halothane, causing it to contract more strongly than normal muscle tissue from non-susceptible people. This type of test is a very accurate way to predict whether a person has MH susceptibility or not. However, the test does require surgery and time to recover (typically 3 days), and it is expensive (approximately \$5,000 USD). In the United States, many insurance companies will pay for the testing if it is needed. Although the test is not available in every state or country, there are at least 40 medical centers worldwide that can perform the test.

Unfortunately, not all MH-susceptible people will learn from their family histories that they have an increased risk for MH before they are exposed to a trigger drug. For these individuals, the diagnosis of MH susceptibility is often made during surgery by the anesthesiologist (a physician specializing in anesthesia) who is providing the anesthesia medications. Other healthcare specialists also may notice symptoms of MH during or after surgery. Symptoms such as rapid breathing, rapid heart rate, and high body temperature can usually be detected with various machines or devices that examine basic body functions during

surgery. Muscle stiffness of the jaw, arms, legs, stomach, and chest may be noticed as well. These symptoms may happen during surgery or even several hours later. If the diagnosis is made during or after surgery, immediate treatment is needed to prevent damage to various parts of the body or death. If a person has a suspicious reaction to anesthesia, he or she may undergo a muscle biopsy to confirm MH susceptibility at a later date.

In spite of the fact that a number of important genes and genetic regions associated with MH susceptibility have been identified, testing a person's DNA for all of the possible changes that may cause this condition is not easily done for affected individuals and their families. Existing genetic testing identifies some changes that have been seen among families with MHS1 and MHS6. Research studies may provide information for families with MHS2, MHS3, MHS4, and MHS5 as well. Sometimes the testing requires DNA from only one affected person, but in other cases, many samples are needed from a variety of family members. Until genetic technology improves, the contracture test that is done on muscle tissue will likely remain the "gold standard" for diagnosis of MH susceptibility.

Treatment and management

The early identification of an MH episode allows for immediate treatment with an antidote called dantrolene sodium. This medication prevents the release of calcium from the sarcoplasmic reticulum, which decreases muscle stiffness and energy production in the cells. If hyperthermia develops, the person's body can be cooled with ice. In addition, the anesthesiologist will change the anesthetic from a trigger drug to a non-trigger drug. Immediate treatment is necessary to prevent serious illness and/or death.

Once a person with definite or suspected MH susceptibility is diagnosed (by an MH episode, muscle biopsy, or family history), prevention of an MH episode is possible. There are many types of non-triggering anesthetic drugs and muscle relaxants that can be used during surgical procedures. The important first step in this process is for people with known or suspected MH susceptibility to talk with their doctors before any surgery so that only non-triggering drugs are used. People with definite or suspected MH susceptibility should always carry some form of medical identification that describes their diagnosis in case emergency surgery is needed. The Malignant Hyperthermia Association of the United States provides wallet-sized emergency medical ID cards for its members.

Prognosis

Early diagnosis and treatment of MH episodes with dantrolene sodium has dramatically improved the prognosis for people who develop MH during or just after

surgery. When the condition was first recognized in the 1960s, no real treatment (other than cooling the person's body) was available, and only 20%–30% of people who developed MH survived. When the antidote (dantrolene sodium) became available in 1979, the survival rate increased to 70%–80%. However, 5%–10% of people who develop MH after exposure to a trigger drug still may die even with proper medication and care. Among those who do survive, some are disabled due to kidney, muscle, or brain damage. The best prognosis exists for people with definite or suspected MH susceptibility who are able to prevent exposures to trigger drugs by discussing their history with their doctors. Improved genetic testing in the future may help identify most or all people with inherited MH susceptibility, so they too may prevent exposures that trigger MH episodes.

Mannosidosis

Definition

Mannosidosis is a rare lysosomal storage disorder of either the alpha or beta form caused by the impaired function of either alpha-mannosidase or beta-mannosidase,

enzymes important in oligosaccharide metabolism. When the body is unable to break down chains of a mannose sugar properly, large amounts of sugar-rich compounds build up in the body cells, tissues, and urine, interfering with normal body functions and the development of the skeleton.

Description

Mannosidosis is a rare genetic disorder that develops in patients whose genes are mutated and are unable to make functional mannosidase enzyme. The enzyme has two forms, alpha and beta, resulting in alpha-mannosidosis and beta-mannosidosis. Alpha-mannosidosis occurs when the gene for the alpha form of the enzyme is mutated or deleted, and beta-mannosidosis occurs when the gene for the beta form of the enzyme is mutated or deleted. A different gene, *MAN2B1* or *MANBA*, controls production of each form of the enzyme. These enzymes are required by lysosomes (structures within the cell where proteins, sugars, and fats are broken down and then released back into the cell to make other molecules). Lysosomes need the enzyme to break down, or degrade, long chains of sugars. Mutations or deletions of the mannosidase enzymes result in the buildup of sugars within lysosomes. The accumulation of these sugars within lysosomes causes impaired cellular function and subsequent cell death.

First described in 1967, alpha-mannosidosis is characterized by mental disabilities, augmented facial features, ataxia, and immune dysfunction. The disorder has been further classified into three clinical subtypes. Infantile (type I) alpha-mannosidosis is a severe disorder that results in intellectual disability and physical deformities, and it can be deadly if not diagnosed and treated quickly. The moderate form (type II) presents before ten years of age with a markedly more gradual development of clinical phenotypes that also include intellectual disability, ataxia, and skeletal abnormalities. Type III, or adult alpha-mannosidosis, is the mildest form of the disorder and develops much more slowly with less effect on mental acuity and fewer skeletal abnormalities.

Beta-mannosidosis was identified nearly 20 years later in 1986. Patients with this form of the disorder are also intellectually disabled but over a wide range of severity, from mild to extreme. Beta-mannosidosis is not well understood, in part because it is such a rare disease. Roughly only 20 people worldwide have been diagnosed with the disorder.

Genetic profile

The two forms of mannosidosis, alpha and beta, are caused by changes on two different genes. Mutations in

the gene *MAN2B1*, on chromosome 19 (19p13.2-q12), results in alpha-mannosidosis. Beta-mannosidosis is caused by mutations in the gene *MANBA*. This gene is on chromosome 4 (4q22-25). Both genes, *MANB* and *MANB1*, are inherited as autosomal recessive traits. Therefore, if a man and woman each carry one defective gene, then 25% of their children will potentially develop the disorder. Previously there was no clear relationship between genotype and the clinically described phenotypes; however, several genome-wide association studies completed in 2015 established more than 127 separate mutations of the *MAN2B1* gene and discovered that one mutation (c.2248C.T [p.Arg750Trp]) accounted for 25% of the disease alleles in unrelated patients. In addition to the identification of these new gene mutation variants, researchers have shown a correlation of disease phenotype severity and the subcellular/lysosomal localization of the mutated/misfolded mannosidase enzyme proteins. A study demonstrated that study participants who had two null mutations—or mutations that caused inappropriate folding of the enzyme protein leading to the inability of the enzyme to reach the lysosomal compartment—were more likely to display more severe phenotypes. Patients who retained one mutant variant facilitating lysosomal entry and subsequent enzymatic function, even if the function was limited, displayed more moderate clinical phenotypes. The discovery that the subcellular location of nonfunctional/reduced-functional enzymes may play a role in the severity of cognitive and physical clinical symptoms may open the door to a more accurate classification system than the current three-tier system.

Demographics

Mannosidosis is a rare disorder, occurring in both men and women at a reported incidence rate of 1 in 500,000 for the alpha form and even less for beta-mannosidosis. The disorder does not affect any particular ethnic group but rather appears in a broad range of people. Alpha-mannosidosis has been studied in Scandinavian, Western and Eastern European, North American, Arabian, African, and Japanese populations. Researchers have identified beta-mannosidosis in European, Hindu, Turkish, Czechoslovakian, Jamaican-Irish, and African families.

Signs and symptoms

The various forms and types of mannosidosis all have one symptom in common: intellectual disability. Other signs and symptoms vary. Infants with alpha-mannosidosis appear normal at birth, but by the end of their first year, they show signs of intellectual disability, which progresses rapidly. Many infants diagnosed die due to degradation of their central nervous system.

KEY TERMS

Autosomal recessive—A pattern of genetic inheritance where two abnormal genes are needed to display the trait or disease.

Enzyme—A protein that catalyzes a biochemical reaction or change without changing its own structure or function.

Enzyme replacement therapy (ERT)—A treatment method used to replace missing enzymes. It is possible to synthesize enzymes and then inject them intravenously into patients.

Hydrolysis—The breakdown of chemical bonds by the addition of water.

Lysosomal storage diseases—A group of more than 40 human genetic disorders that result from defects in lysosomal function.

Lysosome—A membrane-enclosed compartment in cells, containing many hydrolytic enzymes; where large molecules and cellular components are broken down.

Mannose—A type of sugar that forms long chains in the body and is important in metabolism and the glycosylation of proteins.

Mutation—An inherited or *de novo* change in the DNA sequence of the genome.

Individuals with the disorder may develop several symptoms that include dwarfism, shortened fingers, and skeletal changes of the facial region. In these children, the bridge of the nose is flat, the forehead is prominent, ears are large and low set, eyebrows are protruding, and the jaw juts out. Other symptoms include lack of muscle coordination, enlarged spleen and liver, recurring infections, and cloudiness in the back of the eyeball, which is normally clear. These patients often have vacuoles in their white blood cells, a clinical sign that sugars are being stored improperly.

The adult form occurs in 10%–15% of the cases of alpha-mannosidosis. The symptoms in adults are similar to those observed in infants but are less severe and develop more slowly. Patients with adult alpha-mannosidosis are often normal as babies and young children. However, in their childhood or teenage years, intellectual disability and physical symptoms become evident. These patients may also lose their hearing and have pain in their joints.

Beta-mannosidosis is characterized by symptoms that range from mild to severe. In all patients, however,

the most frequent signs are intellectual disability, lung infections, and hearing loss with speech difficulties. In mild cases, patients have red, wart-like spots on their skin. In severe cases, patients may have multiple seizures, and their arms and legs may be paralyzed. Because the symptoms of beta-mannosidosis vary so greatly, researchers suggest that the disorder may frequently be misdiagnosed.

Diagnosis

Both forms of mannosidosis are currently tested by an assay called thin-layer chromatography. This technique screens the patient's urine for abnormal types of sugar. It is a time-consuming and laborious assay that has led to the research and development of more sensitive, high-throughput diagnostic techniques such as high-pressure liquid chromatography (HPLC), matrix-assisted laser desorption/ionization time of flight mass spectrometry (MALDI-TOF), and capillary electrophoresis coupled to a laser-induced fluorescence detector system (CE-LIF), all aimed at a faster and more sensitive diagnosis. It is also possible to perform genetic testing of a patient's blood cells to determine if the enzyme is present. If doctors suspect that a pregnant woman may be carrying a child with mannosidosis, they can use the aforementioned techniques to test cells in the amniotic fluid for enzyme activity.

Treatment and management

The discovery of the gene for alpha-mannosidosis in 1986 led to subsequent attempts to improve the non-effective treatment options available at that time. The first attempt at bone marrow transplantation (BMT) to cure alpha-mannosidosis was performed in 1987 but was unsuccessful and resulted in the death of the patient just 18 weeks after the procedure. Until 2012 no effective treatment options existed, and the symptoms such as intellectual disability and skeletal abnormalities were managed by supportive care, depending on the severity.

Patients with adult alpha-mannosidosis and beta-mannosidosis may show mild intellectual disability or behavior problems (such as depression or aggression) and may be able to function in society with minimal adversity. More severely afflicted individuals may require institutionalization. Skeletal abnormalities may require surgical correction, and recurring infections of the immune system are treated with antibiotics.

Medical advances in 2012 led to the development of viable hematopoietic stem cell transplantation (HSCT). This treatment remains the only efficacious treatment option. Due to the rarity of the disease, only a handful of these transplantations have been performed.

QUESTIONS TO ASK YOUR DOCTOR

- What type of testing is available for a mannosidase disorder, and should I get tested?
- How accurate are diagnostic tests?
- What therapies are available to treat mannosidosis, and what are the associated benefits and risks and costs?
- What is my risk of having children with mannosidosis?
- What resources are available for people who are diagnosed with mannosidosis?

Remediation of symptoms from the procedure is variable among patients, and not all patients survive. Because of the high incidence of harmful side effects and morbidity associated with HSCT, researchers have continued to search for more optimal therapeutic options. Ongoing human clinical trials are testing recombinant human alpha-mannosidase (RhLAMAN) enzyme replacement therapy (ERT), and results from the first 12 months of the 18 month trial showed that RhLAMAN ERT may be a safe new treatment option to decrease levels of oligosaccharide buildup and result in the improvement of motor as well as cognitive functions.

Prognosis

The future for patients with mannosidosis varies with the form of their disorder. Infants with alpha/beta-mannosidosis are not symptomatic at birth, and screening of newborns can identify individuals in need of BMT/ERT. Patients with mild forms of alpha- and beta-mannosidosis often survive into adulthood, but their lives are complicated by intellectual disability and physical deterioration. The advancement of BMT and ERT therapies has significantly improved the prognosis of patients diagnosed with the disorder if identified early enough.

Marfan syndrome

Definition

Marfan syndrome is an inherited disorder of the connective tissue that causes abnormalities of the eyes, cardiovascular system, and musculoskeletal system. It is named for the French pediatrician Antoine Marfan (1858–1942), who first described it in 1896.

Description

Marfan syndrome is sometimes called arachnodactyly, which means "spider-like fingers" in Greek, since one of the characteristic signs of the disease is disproportionately long fingers and toes. Marfan syndrome affects three major organ systems of the body: the heart and circulatory system, the bones and muscles, and the eyes. The genetic mutation responsible for Marfan was discovered in 1991. It affects the body's production of fibrillin, which is a protein that is an important part of connective tissue. Fibrillin is the primary component of the microfibrils that allow tissues to stretch repeatedly without weakening. Because the patient's fibrillin is abnormal, his or

her connective tissues are looser than usual, which weakens or damages the support structures of the entire body.

The most common external signs associated with Marfan syndrome include excessively long arms and legs, with the patient's arm span being greater than his or her height. The fingers and toes may be long and slender, with loose joints that can bend beyond their normal limits. This unusual flexibility is called hypermobility. The patient's face may also be long and narrow, and he or she may have a noticeable curvature of the spine. It is important to note that Marfan patients vary widely in the external signs of their disorder and in their severity; even two patients from the same family may look quite different. Most of the external features of Marfan syndrome become more pronounced as the patient ages, so that diagnosis of the disorder is often easier in adults than in children. In many cases, the patient may have few or very minor outward signs of the disorder, and the diagnosis may be missed until the patient develops ocular or cardiac symptoms.

Marfan syndrome by itself does not affect a person's intelligence or ability to learn. There is, however, some clinical evidence that children with it have a slightly higher rate of attention-deficit and hyperactivity disorder (ADHD) than the general population. In addition, a child with undiagnosed nearsightedness related to the syndrome may have difficulty seeing the blackboard or reading printed materials, and thus may be restless and do poorly in school.

Risk factors

People at highest risk for Marfan syndrome are those who have a family history of the condition. If a person has it, each of their offspring has a 50% chance of having the altered gene that causes the condition. Marfan syndrome that occurs because of spontaneous new mutations (15% to 25% of the cases) cannot be prevented. However, for prospective parents with a family history of Marfan syndrome, genetic counseling is recommended. Older fathers are more likely to have new mutations appear on chromosome 15.

Genetic profile

Marfan syndrome is caused by a mutation in a single gene for fibrillin on chromosome 15, which is inherited in most cases from an affected parent. Only between 15% and 25% of cases result from spontaneous mutations. Mutations of the fibrillin gene, known as *FBNI*, are unique to each family affected by Marfan, which makes rapid genetic diagnosis impossible. More than 3,000 different mutations in this gene have been recorded. The syndrome is an autosomal dominant disorder, which

Five common clinical signs for Marfan syndrome. Pectus excavatum (A) refers to the inward curve of the chest. Positive thumb sign (B) is the appearance of the thumb tip when making a closed fist. Positive elbow sign (C) is the ability to touch one's elbows behind their back. Scoliosis (D) is a marked side-to-side curvature of the spine, and kyphosis (E) is the hunchback form resulting from an outward curvature of the spine (Gale)

means that someone who has it has a 50% chance of passing it on to any offspring.

Another important genetic characteristic of Marfan syndrome is its variable expression. This term means that the mutated *FBNI* gene can produce a variety of symptoms of very different degrees of severity, even in members of the same family.

Demographics

Marfan syndrome is one of the more common inheritable disorders. It appears that about one person in every 5,000 has Marfan syndrome including men and women of all races and ethnic groups.

Signs and symptoms

Cardiac and circulatory abnormalities

The most important complications of Marfan syndrome are those affecting the heart and major blood vessels; some are potentially life-threatening. About 90% of Marfan patients will develop cardiac complications. These include:

- **Aortic enlargement:** This is the most serious potential complication of Marfan syndrome. Because of the abnormalities of the patient's fibrillin, the walls of the aorta (the large blood vessel that carries blood away from the heart) are weaker than normal and tend to stretch and bulge out of shape. This stretching increases the likelihood of an aortic dissection, which is a tear or separation between the layers of tissue that make up the aorta. An aortic dissection usually causes severe pain in the abdomen, back, or chest, depending on the section of the aorta that is affected. Rupture of the aorta is a medical emergency requiring immediate surgery and medication.
- **Aortic regurgitation:** A weakened and enlarged aorta may allow some blood to leak back into the heart during each heartbeat. This condition is called aortic regurgitation. Aortic regurgitation occasionally causes shortness of breath during normal activity. In serious cases, it causes the left ventricle of the heart to enlarge and may eventually lead to heart failure.
- **Mitral valve prolapse:** Between 75% and 85% of patients with Marfan syndrome have loose or "floppy" mitral valves, which are the valves that separate the chambers of the heart. When these valves do not cover the opening between the chambers completely, the condition is called mitral valve prolapse. Complications of mitral valve prolapse include heart murmurs and arrhythmias. In rare cases, mitral valve prolapse can cause sudden death.
- **Infective endocarditis:** An infection of the endothelium, the tissue that lines the heart. In patients with Marfan syndrome, it is the abnormal mitral valve that is most likely to become infected.

The hands of a person suffering from Marfan's syndrome, showing abnormally elongated and slender fingers. A normal hand is shown at right for comparison. Marfan's syndrome is an inherited disorder of connective tissue characterized by long, slender fingers and toes and excessive height. Heart defects and dislocations of the lenses of the eye may also be present. (John Radcliffe Hospital/Science Source)

- **Other complications:** Some patients with Marfan syndrome develop cystic disease of the lungs or recurrent spontaneous pneumothorax, a condition in which air accumulates in the space around the lungs. Many patients eventually develop emphysema.

Musculoskeletal abnormalities

Marfan syndrome causes an increase in the length of the patient's bones, with decreased support from the ligaments that hold the bones together. As a result, the patient may develop various deformities of the skeleton or disorders related to the relative looseness of the ligaments, also known as hypermobility.

Disorders of the spine

- **Scoliosis (curvature of the spine):** A disorder in which the vertebrae that make up the spine twist out of line from side to side into an S-shape or a spiral. It is caused by a combination of the rapid growth of children with Marfan, and the looseness of the ligaments that help the spine to keep its shape.
- **Kyphosis:** An abnormal outward curvature of the spine, sometimes called hunchback when it occurs in the upper back. Patients with Marfan syndrome may develop kyphosis either in the upper (thoracic) spine or the lower (lumbar) spine.
- **Spondylolisthesis:** The medical term for a forward slippage of one vertebra on the one below it. It produces an ache or stiffness in the lower back.

- **Dural ectasia:** The dura is the tough, fibrous outermost membrane covering the brain and the spinal cord. The weak dura in patients with Marfan syndrome swells or bulges under the pressure of the spinal fluid. This swelling is called ectasia. In most cases, dural ectasia occurs in the lower spine, producing lower back ache, a burning feeling, or numbness or weakness in the legs.

Disorders of the chest and lower body

- **Pectus excavatum:** A malformation of the chest in which the patient's breastbone, or sternum, is sunken inward. It can cause difficulties in breathing, especially if Marfan has affected the heart, spine, and lung. It also usually causes concerns about appearance.
- **Pectus carinatum:** In other patients with Marfan syndrome, the sternum is pushed outward and narrowed. Although pectus carinatum does not cause breathing difficulties, it can cause embarrassment about appearance. A few patients may have a pectus excavatum on one side of their chest and a pectus carinatum on the other.
- **Foot disorders:** Patients with Marfan syndrome are more likely to develop pes planus (flat feet) or so-called "claw" or "hammer" toes than people in the general population. They are also more likely to have chronic pain in their feet.
- **Protrusio acetabulae:** The acetabulum is the socket of the hip joint. In patients with Marfan syndrome, the acetabulum becomes deeper than normal during growth for reasons that are not yet understood. Although protrusio acetabulae does not cause problems during childhood and adolescence, it can lead to a painful form of arthritis in adult life.

Disorders of the eyes and face

Although the visual problems that are related to Marfan syndrome are rarely life-threatening, they are important in that they may be the patient's first indication of the disorder. Eye disorders related to the syndrome include the following:

- **Myopia (nearsightedness):** Most patients with Marfan develop nearsightedness, usually in childhood.
- **Ectopia lentis:** The medical term for dislocation of the lens of the eye. Between 65% and 75% of patients with Marfan syndrome have dislocated lenses. This condition is an important indication for diagnosis of the syndrome, because there are relatively few other disorders that produce it.
- **Glaucoma:** This condition is much more prevalent in patients with Marfan syndrome than in the general population.

- **Cataracts:** Patients with Marfan are more likely to develop cataracts, and to develop them much earlier in life, sometimes as early as age 40.
- **Retinal detachment:** Patients with Marfan syndrome are more vulnerable to this disorder because of the weakness of their connective tissues. Untreated retinal detachment can cause blindness. The danger of retinal detachment is an important reason for patients to avoid contact sports or other activities that could cause a blow on the head or being knocked to the ground.
- **Other facial problems:** Patients with Marfan syndrome sometimes develop dental problems related to crowding of the teeth caused by a high-arched palate and a narrow jaw.

Other disorders

- **Striae:** Stretch marks in the skin caused by rapid weight gain or growth; they frequently occur in pregnant women, for example. Patients with Marfan syndrome often develop striae over the shoulders, hips, and lower back at an early age because of rapid bone growth. Although the patient may be self-conscious about the striae, these are not a danger to health.
- **Obstructive sleep apnea:** Refers to partial obstruction of the airway during sleep, causing irregular breathing and sometimes snoring. In patients with Marfan syndrome, obstructive sleep apnea is caused by the unusual flexibility of the tissues lining the patient's airway. This disturbed breathing pattern increases the risk of aortic dissection.

Diagnosis

There is no objective diagnostic test for Marfan syndrome, in part because the disorder does not produce any measurable biochemical changes in the patient's blood or body fluids, or cellular changes that could be detected from a tissue sample. The current standard of diagnostic criteria are set forth in the Ghent-2 nosology. This set of diagnostic criteria was updated in 2010 from the previously established Ghent-1 nosology described in 1996.

Examination

The diagnosis is established by taking a family history and a thorough examination of the patient's eyes, heart, and bone structure. The examination includes a slit-lamp eye examination by an ophthalmologist, and a work-up of the patient's spinal column by an orthopedic specialist. The importance of the slit-lamp examination is that it allows the doctor to detect a dislocated lens, which is a significant indication of the syndrome.

Tests

In terms of the cardiac examination, a standard electrocardiogram (EKG) is not sufficient for diagnosis; only the echocardiogram can detect possible enlargement of the aorta. Other tests include using magnetic resonance imaging (MRI) and computed tomography (CT) to check the heart valves and aorta. These scans also are used to check for dural ectasia, a typical complication of Marfan syndrome.

The symptoms of Marfan syndrome in some patients resemble the symptoms of homocystinuria, which is an inherited disorder marked by extremely high levels of homocysteine in the patient's blood and urine. This possibility can be excluded by a urine test.

In other cases, the diagnosis remains uncertain because of the mildness of the patient's symptoms, the absence of a family history of the syndrome, and other variables. These borderline conditions are sometimes referred to as marfanoid syndromes.

Treatment and management

Traditional

The treatment and management of Marfan syndrome are tailored to the specific symptoms of each patient. Some patients find that the syndrome has little impact on their overall lifestyle; others have found their lives centered on the disorder.

After a person has been diagnosed with Marfan syndrome, he or she should be monitored with an echocardiogram every six months until it is clear that the aorta is not growing larger. After that, the patient should have an echocardiogram once a year. If the echocardiogram does not allow the physician to visualize all portions of the aorta, CT or MRI may be used. In cases involving a possible aortic dissection, the patient may be given a transesophageal echocardiogram (TEE).

Children diagnosed with Marfan syndrome should be checked for scoliosis by their pediatricians at each annual physical examination. The doctor simply asks the child to bend forward while the back is examined for changes in the curvature. In addition, the child's spine should be x-rayed in order to measure the extent of scoliosis or kyphosis. The curve is measured in degrees by the angle between the vertebrae as seen on the x-ray. Curves of 20° or less are not likely to become worse. Curves between 20° and 40° are likely to increase in children or adolescents. Curves of 40° or more are highly likely to worsen, even in an adult, because the spine is so badly imbalanced that the force of gravity will increase the curvature.

KEY TERMS

Autosomal dominant—Refers to the pattern of inheritance in which only one copy of an allele that causes a disorder needs to be passed down to offspring for those offspring to also have the disorder phenotype.

Fibrillin—A glycoprotein secreted by fibroblasts into the extracellular matrix necessary for the deposition of elastin and the proper function of elastic fibers found in connective tissues.

Hypermobility—The ability to stretch one's joints farther than normal.

Nosology—A branch of medicine that aims to classify diseases by means of disease etiology (cause), pathogenesis (mechanism), and/or symptoms.

Scoliosis in 20° and 40° in children is usually treated with a back brace. The child must wear this appliance about 23 hours a day until growth is complete. If the spinal curvature increases to 40° or 50°, the patient may need surgery in order to prevent lung problems, back pain, and further deformity. Surgical treatment of scoliosis involves straightening the spine with metal rods and fusing the vertebrae in the straightened position.

Spondylolisthesis is treated with a brace in mild cases. If the slippage is more than 30°, the slipped vertebra may require surgical realignment.

Dural ectasia can be distinguished from other causes of back pain on an MRI. Mild cases are usually not treated. Medication or spinal shunting to remove some of the spinal fluid are used to treat severe cases.

Pectus excavatum and pectus carinatum can be treated by surgery. In pectus excavatum, the deformed breastbone and ribs are raised and straightened by a metal bar. After four to six months, the bar is removed in an outpatient procedure.

Protrusio acetabulae may require surgery in adult life to provide the patient with an artificial hip joint, if the arthritic pains are severe.

Patients with Marfan syndrome should consider wearing shoes with low heels, special cushions, or orthotic inserts. Foot surgery is rarely necessary.

Drugs

A patient may be given drugs called beta-blockers to slow down the rate of aortic enlargement and decrease the

risk of dissection by lowering the blood pressure and decreasing the forcefulness of the heartbeat. The most commonly used beta-blockers in patients with Marfan syndrome are propranolol (Inderal) and atenolol (Tenormin). Patients who are allergic to beta-blockers may be given a calcium blocker such as verapamil.

Because patients with Marfan syndrome are at increased risk for infective endocarditis, they must take a prophylactic dose of an antibiotic before having dental work or minor surgery, as these procedures may allow bacteria to enter the bloodstream. Penicillin and amoxicillin are the antibiotics most often used.

Pain in the feet or limbs is usually treated with a mild analgesic such as acetaminophen.

Alternative

Surgery may be necessary if the width of the patient's aorta increases rapidly or reaches a critical size (about 2 in., 5 cm). The most common surgical treatment involves replacing the patient's aortic valve and several inches of the aorta itself with a composite graft, which is a prosthetic heart valve sewn into one end of a Dacron tube. This surgery has been performed widely since about 1985; most patients who have had a composite graft have not needed additional surgery.

Patients who have had a valve replaced must take an anticoagulant medication, usually warfarin (Coumadin), in order to minimize the possibility of a clot forming on the prosthetic valve.

Visual and dental concerns

Patients with Marfan syndrome should have a thorough eye examination, including a slit-lamp examination, to test for dislocation of the lens as well as nearsightedness. Dislocation can be treated by a combination of special glasses and daily use of 1% atropine sulfate ophthalmic drops, or by surgery.

Because patients with Marfan syndrome are at increased risk of glaucoma, they should have the fluid pressure inside the eye measured every year as part of an eye examination. Glaucoma can be treated with medications or with surgery.

Cataracts are treated with increasing success by implant surgery. It is important to seek treatment at medical centers with eye surgeons who are familiar with the possible complications of cataract surgery in patients with Marfan syndrome.

All persons with Marfan syndrome should be taught to recognize the signs of retinal detachment (sudden blurring of vision in one eye becoming progressively worse

QUESTIONS TO ASK YOUR DOCTOR

- How do you plan to treat my Marfan syndrome?
- Are there treatment options?
- Is surgery necessary?
- What is the expected outcome?
- How do people inherit Marfan syndrome?

without pain or redness) and to seek professional help immediately.

Children with Marfan syndrome should be evaluated by their dentist at each checkup, for crowding of the teeth and possible misalignment, and referred to an orthodontist if necessary.

People with Marfan syndrome should avoid sports or occupations that require heavy weight lifting, rough physical contact, or rapid changes in atmospheric pressure (e.g., scuba diving). Weight lifting increases blood pressure, which in turn may enlarge the aorta. Rough physical contact may cause retinal detachment. Sudden changes in air pressure may produce pneumothorax. Regular noncompetitive physical exercise, however, is beneficial for patients with Marfan syndrome. Good choices include brisk walking, shooting baskets, and slow-paced tennis.

Social and lifestyle issues

Smoking is particularly harmful for patients with Marfan, because it increases their risk of emphysema.

In the past, women with Marfan syndrome were advised to avoid pregnancy because of the risk of aortic enlargement or dissection. The development of beta-blockers and echocardiograms, however, now allows doctors to monitor patients throughout pregnancy. It is recommended that patients have an echocardiogram during each of the three trimesters of pregnancy. Normal, vaginal delivery is not necessarily more stressful than a Caesarian section, but patients in prolonged labor may have a Caesarian birth to reduce strain on the heart. A pregnant woman with Marfan syndrome should also receive genetic counseling regarding the 50% risk of having a child with the syndrome.

Children and adolescents with Marfan syndrome may benefit from supportive counseling regarding appearance, particularly if their symptoms are severe and cause them to withdraw from social activities. Families may wish to seek counseling regarding the effects of

the syndrome on relationships within the family. Many people respond with guilt, fear, or blame when a genetic disorder is diagnosed in the family, or they may overprotect the affected member. Support groups are often good sources of information about Marfan syndrome; they can offer helpful suggestions about living with it as well as emotional support.

Prognosis

The prognosis for patients with Marfan syndrome has improved markedly. The life expectancy of people with the syndrome had increased to 72 years, up from 48 years in 1972. This dramatic improvement is attributed to new surgical techniques, improved diagnosis, and new techniques of medical treatment.

The most important single factor in improving the patient's prognosis is early diagnosis. The earlier that a patient can benefit from the new techniques and lifestyle modifications, the more likely he or she is to have a longer life expectancy.

In 2021, researchers have developed an animal model that may eventually lead to a treatment to prevent lens detachment in individuals who have eye complications. In addition, clinical trials are underway to treat various symptoms of Marfan syndrome. Participation in a clinical trial is voluntary and at no cost to the participant. All clinical trials receiving U.S. government funding, and some supported by private industry, are posted at <https://www.clinicaltrials.gov>. Foreign trials are listed at <https://www.orpha.net>.

Marshall-Smith syndrome

Definition

Marshall-Smith syndrome is a childhood condition involving specific facial characteristics, bone maturation that is advanced for the individual's age, failure to grow and gain weight appropriate for the individual's age, and severe respiratory (breathing) problems.

Description

Marshall-Smith syndrome (MSS) was first described in two males seen in 1971 by Drs. Marshall, Graham, Scott, and Smith. They noticed changes in the skeletal system of these patients. Bones normally mature through several stages, naturally progressing through these stages with time. Specifically, a young child's bones have more cartilage and less calcium deposits than an adult's bones. A child's bones appear less "dense" on an x-ray than an adult's bones. A constant feature of MSS is skeletal maturation that is advanced for age. For example, in 1993 a newborn child with MSS was found to have the bone age of a three-year-old child.

Specific facial features in MSS include a wide and prominent forehead, protruding and widely spaced eyes, a very small chin, and a small, upturned nose. Because individuals may not gain weight or grow well, they are often smaller than other children of the same age. There are often problems with structures in the respiratory tract (such as the larynx and trachea) and this can lead to difficulty with breathing. Pneumonia, or a lung infection, is common and can occur several times.

KEY TERMS

Cartilage—Supportive connective tissue which cushions bone at the joints or which connects muscle to bone.

Corpus callosum—A thick bundle of nerve fibers deep in the center of the forebrain that provides communication between the right and left cerebral hemispheres.

Gastrostomy—The construction of an artificial opening from the stomach through the abdominal wall to permit the intake of food.

Hirsutism—The presence of coarse hair on the face, chest, upper back, or abdomen in a female as a result of excessive androgen production.

Larynx—The voice box, or organ that contains the vocal cords.

Phalanges—Long bones of the fingers and toes, divided by cartilage around the knuckles.

Trachea—Long tube connecting from the larynx down into the lungs, responsible for passing air.

Tracheostomy—An opening surgically created in the trachea (windpipe) through the neck to improve breathing.

Umbilical hernia—Protrusion of the bowels through the abdominal wall, underneath the navel.

Significant mental and physical delays are almost always expected in MSS. Since children with MSS are often hospitalized for long periods of time to help treat respiratory problems, they may be slower to do physical things like crawling or walking.

No two patients with MSS have the exact same symptoms, as there is some variability with the condition. There are no alternate names for Marshall-Smith syndrome, though it is sometimes incorrectly referred to as Weaver syndrome, a separate condition with similar symptoms.

Families with MSS can be put under a great deal of stress, because long-term hospitalizations in the intensive care unit are common for children with MSS.

Genetic profile

The vast majority of people with MSS are unique in their family; there is usually no family history of the condition. Because of this, MSS is thought to be a random, sporadic event when it occurs. No specific gene has been associated with MSS, and other genetic background is

still largely unknown. Standard genetic testing, such as chromosome analysis and metabolic studies, typically are normal for patients with MSS.

In 1999, a group in Saudi Arabia reported a young girl with features of MSS who had a chromosome abnormality. She was found to have some duplication of the material on a region of chromosome 2. This has led researchers to believe that the gene for MSS may actually be on chromosome 2. This is the only individual with MSS found to have a chromosome abnormality. Current research is under way to determine the exact genetic cause for MSS.

Demographics

Marshall-Smith syndrome is very rare in the general population. In fact, no statistical rates are available for the condition. It appears to be present across the world, affecting males and females equally.

Signs and symptoms

The most medically serious complication in MSS is the associated respiratory problems. Structures in the respiratory system, such as the larynx and trachea, may not function properly because they can be “floppy,” soft, and less muscular than usual. Because of this, airways can become plugged or clogged, since air does not move through to clear them like usual. Mucus may start collecting, causing an increased amount of bacteria that can lead to pneumonia. Ear infections are common, because the bacteria can spread to the ears as well. Internal nasal passages may be narrower in people with MSS, which can pose difficulty with breathing.

Children with MSS may have problems with eating, due to similar reasons that they may have difficulty breathing. Additionally, they may have a weak “suck” and “swallowing” reflex, normally controlled by muscular movements. As mentioned earlier, another feature of MSS is lack of proper growth and weight gain. This can be in part due to the difficulty in feeding for these individuals, though they are often very small even at birth.

Advanced bone age is present in all people with MSS. In particular, the bones of someone with MSS appear more dense on an x-ray than they should, according to their age. While x-rays of their hands and wrists often determine a person’s “bone age,” people with MSS often have a generalized advanced bone age within their entire skeleton. They may also have broad middle phalanges of the hand, which can be seen on an x-ray.

Facial characteristics of people with MSS include those mentioned earlier, but other features may also occasionally be present. These can be blue-tinged sclerae (the

QUESTIONS TO ASK YOUR DOCTOR

- What are the medical problems my child is likely to have to confront as a result of having Marshall-Smith syndrome?
- What is her life expectancy likely to be as a result of this condition?
- Are there medications or procedures that can be provided to make her life more comfortable?
- Are there organizations for parents of children with Marshall-Smith syndrome?

white sections of the eyes), a large head circumference (measurement around the head), and a small, triangle-shaped face (with the point of the triangle being at the chin).

Occasionally, creases in the hands are deeper than usual in people with MSS. The first (big) toe can be longer and bigger than usual. Additional features include hirsutism and an umbilical hernia. Hearing loss can sometimes occur. Ears may be larger, have a crumpled appearance, or be lower on the head than usual.

Changes in the brain can occur in MSS. An individual was reported in 1997 to have a smaller optic nerve (the nerve that connects the eyes to the brain) than usual, and had some vision problems as a result. Some children may be missing the corpus callosum, a structure in the brain. Mental and physical delays are commonly present in MSS, and are usually quite significant. These may in part be due to the brain abnormalities that are sometimes seen. There may be partial to complete lack of speech for individuals with MSS, another sign of the mental delays.

Diagnosis

Because there is no genetic testing available for Marshall-Smith syndrome, all individuals have been diagnosed through a careful physical examination and study of their medical history.

Advanced skeletal age can be seen on x-rays of the patient's hands and wrists, since this is the typical way to assess bone age. A full x-ray survey of the body is a good way to assess age of other bones as well. Advanced bone age is always seen in Marshall-Smith syndrome, but it may also be present in other genetic syndromes. Sotos syndrome involves similar skeletal findings, but individuals are generally larger than usual and can have mental delays. Weaver syndrome includes advanced skeletal

maturation, but individuals are often larger than usual and have other specific facial characteristics (such as very narrow, small eyes). These and other conditions can be ruled out if the respiratory complications and facial characteristics seen in MSS are not present.

Treatment and management

As mentioned earlier, long hospitalizations are common for people with MSS. Most of these involve treating severe respiratory complications of MSS. These types of complications often necessitate placing a tracheotomy to assist with breathing. Manual removal of the mucus buildup by suctioning near the tracheotomy is common. Frequent pneumonia is common, and intravenous antibiotics are often the treatment, as in people without MSS. There is no specific treatment for the advanced bone age.

Because feeding can be difficult for children with MSS, a gastrostomy is often needed, and feeding is done directly through the gastrostomy tube. It is a challenge to make sure children with MSS maintain proper growth, and sometimes a gastrostomy is the only way to achieve this.

Prognosis

Marshall-Smith syndrome is considered a childhood condition because affected individuals do not typically survive past childhood. There is no long-term research on the disease due to its being rare and not typically present in adults.

Most children with MSS die in early childhood, often by three years of age, largely due to severe respiratory complications, and infections that may result from them. There have been reports of children surviving until age seven or eight, but these children did not have severe respiratory problems. These children give hope that the condition is variable, and not every person diagnosed with the condition will have a severely shortened lifespan.

Marshall syndrome

Definition

Marshall syndrome is a very rare genetic disorder with an autosomal dominant pattern that equally affects males and females. It is caused by an abnormality in collagen, which is a key part of connective tissue.

Description

Marshall syndrome was first described by Dr. D. Marshall in 1958, and it has been studied periodically by researchers since then. The disease is most apparent in the facial features of those affected, which include an upturned nose; eyes spaced widely apart, making them appear larger than normal; and a flat nasal bridge. This facial formation gives subjects a childlike appearance. The upper part of the skull is unusually thick, and deposits of calcium may appear in the cranium. Patients may also have palate abnormalities. In addition, they may experience early osteoarthritis, particularly in the knees.

Myopia (nearsightedness), cataracts, and glaucoma are common in Marshall syndrome. Moderate to severe hearing loss is often preceded by many incidents of otitis media (middle ear infection) and can occur in children as young as age three.

In the 40 years following Dr. Marshall’s discovery, some physicians argued that Marshall syndrome is

KEY TERMS

Cataract—A clouding of the eye lens or its surrounding membrane that obstructs the passage of light, resulting in blurry vision. Surgery may be performed to remove the cataract.

Collagen—The main supportive protein of cartilage, connective tissue, tendon, skin, and bone.

Glaucoma—An increase in the fluid eye pressure, eventually leading to damage of the optic nerve and ongoing visual loss.

Myopia—Nearsightedness; difficulty seeing objects that are far away.

Osteoarthritis—A degenerative joint disease that causes pain and stiffness.

Saddle nose—A sunken nasal bridge.

actually a subset of Stickler syndrome, a more common genetic disorder. Individuals with both syndromes have similar facial features and symptoms. Other experts have argued against this view, stating that Marshall syndrome is a distinct disorder on its own. For example, most patients with Stickler syndrome have cataracts, while this problem is less common among those with Marshall syndrome. In addition, most subjects with Marshall syndrome have moderate to severe hearing loss, which rarely occurs among those with Stickler syndrome, who have normal hearing.

Genetic research performed in 1998 and 1999 revealed that both sides were correct. There are clear genetic differences between the two syndromes. There are also patients who have apparent overlaps of both syndromes.

In 1998, a study used genetic testing to establish that a collagen genetic mutation on *COL11A1* caused Marshall syndrome and that a change on *COL2A1* caused Stickler syndrome. A 2007 study found that other types of mutations on *COL11A1* could cause either syndrome.

A study in 1999 described a genetic study of 30 patients from Europe and the United States, all of whom were suspected to have either Marshall or Stickler syndrome. These genetic findings confirmed those of the previous (1998) study. Twenty-three novel mutations of *COL11A1* and *COL2A1* were found among the subjects. Some patients had genetic overlaps of both Marshall and Stickler syndromes.

Physical differences were also noted between the two syndromes. For example, all the patients with Marshall

syndrome had moderate to severe hearing loss, while none of the patients with Stickler syndrome had hearing loss. About half the patients with overlapping disorders of both diseases had hearing loss. All the patients with Marshall syndrome had short noses, compared to about 75% of the patients with Stickler syndrome. Palate abnormalities occur in all patients with Stickler syndrome, compared to only about 80% of those with Marshall syndrome. Also, about a third of the Stickler patients had dental abnormalities, compared to 11% of the patients with Marshall syndrome. Those with Stickler (71%) had a higher percentage of cataracts than those with Marshall syndrome (40%). Patients with Marshall syndrome were much more likely to have short stature than those with Stickler syndrome.

Genetic profile

The gene name for Marshall syndrome is Collagen, Type XI, alpha 1. The gene symbol is *COL11A1*. The chromosomal location is 1p21. Marshall syndrome is an autosomal dominant genetic trait, and the risk of an affected parent transmitting the gene to the child is 50%. Human traits are the product of the interaction of two genes from that condition, one received from the father and one from the mother. In dominant disorders, a single copy of the abnormal gene (received from either parent) dominates the normal gene and results in the appearance of the disease. The risk of transmitting the disorder from affected parent to offspring is 50% for each pregnancy regardless of the gender of the resulting child.

Demographics

Because of the rarity of this disease, very little demographic data is available. Fewer than 100 cases of individuals with this syndrome have been reported worldwide in medical literature. Some cases are probably undiagnosed because of the high expense of genetic testing. It is known that Marshall syndrome presents in infancy or early childhood and severe symptoms such as hearing loss and cataracts manifest before the age of ten years. Adults with the syndrome retain the facial traits that are characteristic of this disease, such as flat nose, large nasal bridge, and widely spaced eyes. Among those with Stickler syndrome, in contrast, these distinctive facial characteristics diminish in adulthood.

Signs and symptoms

Characteristic features of this disease are short upturned nose with a flat nasal bridge. Some patients also have glaucoma, crossed eyes, detached retinas, and protruding upper teeth. Patients often have short stature compared to other family members without the disease.

QUESTIONS TO ASK YOUR DOCTOR

- What is collagen, and what role does it play in Marshall syndrome?
- What are the most prominent signs and symptoms associated with Marshall syndrome?
- What kinds of treatment are available for the most serious symptoms of Marshall syndrome?
- Is there currently any type of research being conducted on a cure for Marshall syndrome?

Diagnosis

Individuals are diagnosed by their features as well as by the very early onset of serious eye and ear disease. Because Marshall syndrome is an autosomal dominant hereditary disease, physicians can also note the characteristic appearance of the biological parent of the child. Genetic testing is costly; thus, it is not ordered for most people. As a result, people may be diagnosed as possible Marshall syndrome or possible Stickler syndrome, based on their symptoms and appearance.

Treatment and management

Marshall syndrome cannot be cured; however, the symptoms caused by the disease should be treated. Children with Marshall syndrome should have annual eye and ear checkups because of the risk for cataracts and hearing loss. Cataract surgery is needed if cataracts develop. At present, the only treatment for the progressive hearing loss is a hearing aid. The flat “saddle nose” can be altered with cosmetic surgery. If a child with Marshall syndrome has osteoarthritis, doctors may advise against contact sports.

Prognosis

As patients with Marshall syndrome age, vision and hearing problems generally worsen. Many also develop osteoarthritis at an earlier age than do patients without Marshall syndrome, such as in the teens or 20s. Because there are so few identified cases, the life expectancy of afflicted individuals is unknown.

MCAD deficiency

Definition

Medium chain acyl-CoA dehydrogenase (MCAD) deficiency is a rare genetic disorder characterized by a deficiency of the MCAD enzyme. This enzyme is responsible for the breakdown of certain fatty acids into chemical forms that are useable by the human body. MCAD

deficiency accounts for approximately 1 to 3 of every 100 cases of sudden infant death syndrome (SIDS). MCAD deficiency is transmitted through a non-sex linked (autosomal) recessive trait. The first recognized cases of MCAD deficiency were reported in 1982.

Description

MCAD is one of four enzymes in the mitochondria of the cells that are responsible for the breakdown of medium-chain fatty acids into acetyl-CoA. Medium-chain fatty acids are defined as fatty acids containing between 4 and 14 carbon atoms. Acetyl-CoA, the desired product of the breakdown of these fatty acids, is a two-carbon molecule. MCAD is the enzyme responsible for the breakdown of straight-chain fatty acids with 4 to 14 carbons. There are two other enzymes that are responsible for the breakdown of short straight-chain (less than 4 carbons) fatty acids, and long straight-chain (more than 14 carbons) fatty acids. These other two enzymes are not able to take over the function of MCAD when MCAD is deficient.

Individuals affected with MCAD deficiency produce a form of the MCAD enzyme that is not nearly as efficient as the normal form of MCAD. This lack of efficiency results in a greatly diminished, but still functional, capability to break down medium-chain fatty acids.

Genetic profile

The gene that is responsible for the production of MCAD is located on chromosome 1 at 1p31. Twenty-six different mutations of this gene have been identified as causing MCAD deficiency; however, 95%–98% of all cases are the result of a single point mutation. In this

MCAD deficiency: pedigree analysis chart. (Gale)

mutation, adenosine is substituted for guanine in base 985 (G985A), which causes a substitution of lysine (AAA) by glutamic acid (GAA) in residue 329 of the MCAD protein.

MCAD deficiency is a recessive disorder. This means that in order for a person to be affected with MCAD deficiency, he or she must carry two abnormal copies of the *MCAD* gene. In a population of individuals known to be affected with the G985A mutation, 81% were found to be homozygous for this mutation (two chromosomes, each with the same mutation). The remaining 19% were found to be heterozygous for the G985A mutation (only one chromosome carried the G985A mutation), but their other chromosomes carried one of the other MCAD gene mutations.

Demographics

MCAD deficiency is estimated to occur in approximately 1 out of every 13,000 to 20,000 live births. This estimate is confounded to a certain degree by the fact that up to 25% of all individuals affected with MCAD deficiency die the first time they exhibit any symptoms of the disease. Many of these children are often misdiagnosed with either sudden infant death syndrome (SIDS) or Reye syndrome. Unless an autopsy is performed, MCAD generally goes undetected in these individuals; and, even then, unless the physician performing the autopsy is familiar with MCAD deficiency, the cause of death may still be misreported.

MCAD deficiency is seen almost exclusively in Caucasians of Northern European descent (this includes people from every European country not bordering the Mediterranean Sea). Approximately 80% of the Caucasian population of the United States can be considered to be a part of this subpopulation. In this subpopulation, it is estimated that 1 in every 40 to 100 people is a carrier of the G985A mutation, and 1 in every 6,500 to 20,000 people is homozygous in this mutation. Homozygous individuals (carriers of two sets of the G985A mutation) should be affected with MCAD deficiency; however, the incidence rate of MCAD deficiency is lower than that predicted from the carrier populations. There are two possible reasons for the lower number of observed cases of MCAD deficiency than the carrier data suggests should occur. First, many individuals with MCAD deficiency may be misdiagnosed. Secondly, there may be a significant number of homozygous people who for unknown reasons remain unaffected (asymptomatic).

As a comparison, 1 in every 29 Caucasians is a carrier for cystic fibrosis, but only 1 in every 3,300 people in this subpopulation develops the disease.

The high frequency of a single mutation leading to MCAD deficiency, combined with the extreme similarity of the other known mutations to this mutation and the

high concentration of MCAD deficiency within a single subpopulation, suggests a founder effect from a single person in a Germanic tribe.

Because MCAD deficiency is a recessive disease, both parents must be carriers of this trait in order for their children to be affected. If both parents carry a copy of the mutated gene, there is a 25% likelihood that their child will be homozygous for MCAD deficiency. Genetically, the probability that an affected person will have a sibling who is also affected is also 25%. In population studies of known MCAD deficient individuals, it has been observed that an average of 32% of these individuals have at least one sibling either known to be affected with MCAD deficiency or to have died with a misdiagnosis of SIDS.

Signs and symptoms

There is no classic set of symptoms that characterize MCAD deficiency. The severity of symptoms observed in individuals affected with MCAD deficiency ranges from no symptoms at all (asymptomatic) to the occurrence of death upon the first onset of symptoms. The first symptoms of MCAD deficiency generally occur within the first three years of life. The average age of onset of the first symptoms is one year of age. Some individuals become symptomatic prior to birth. The onset of symptoms in adults is extremely rare.

Lethargy and persistent vomiting are the most typical symptoms of MCAD deficiency. The first episode of symptoms is generally preceded by a 12 to 16 hour period of stress. Most affected individuals show intermittent periods of low blood sugar (hypoglycemia) and higher than normal amounts of ammonia in the blood (hyperammonemia). An abnormally large liver (hepatomegaly) is also associated with MCAD deficiency.

Approximately half of all individuals showing symptoms of MCAD deficiency for the first time experience respiratory arrest, cardiac arrest, and/or sudden infant death. Between 20% and 25% of all MCAD deficiency affected infants die during their first episodes of symptoms.

Some individuals affected with MCAD deficiency are affected with a degenerative disease of the brain and central nervous system (encephalopathy). Seizures, coma, and periods of halted breathing (apnea) have also been seen in people with MCAD deficiencies.

Long-term symptoms of MCAD deficiency may include: attention deficit disorder (ADD), cerebral palsy, mental retardation, and/or developmental delays.

The severity of the symptoms associated this MCAD deficiency is linked to the age of the person when the symptoms first happen. The risk of dying from an onset of the disease is slightly higher in individuals who show the first symptoms after the age of one year. The highest risk ages

are the ages of 15 to 26 months. Seizures and encephalopathy are most frequently seen in affected individuals between the ages of 12 and 18 months. Seizures at these ages are often associated with future death during a symptomatic episode, recurrent seizures throughout life, the development of cerebral palsy, and/or the development of speech disabilities.

Diagnosis

The Departments of Health in Massachusetts and North Carolina require mandatory newborn screening for MCAD deficiency. California has a voluntary newborn screening policy. Additionally, Neo Gen Screening offers voluntary newborn screening at birthing centers throughout the Northeastern United States.

These newborn screening methods employ either a tandem mass spectrometry (MS/MS) blood test method or a PCR/FRET analysis. The MS/MS test discovers the presence of the G985A mutation in the *MCAD* gene by the difference in molecular weight in this gene versus the molecular weight of the normal *MCAD* gene.

In the PCR/FRET test, a sample of blood is drawn and the DNA is extracted. This DNA is then reproduced multiple times by the polymerase chain reaction (PCR amplification). Once enough sample has been made, the sample is labeled with a fluorescent chemical that binds specifically to the region of chromosome 1 that contains the *MCAD* gene. How this fluorescent chemical binds to the *MCAD* gene region containing the G985A mutation allows the identification of homozygous G985A, heterozygous G985A, and normal (no G985A mutations) *MCAD* genes (FRET analysis).

An older method for the detection of MCAD deficiency is a urine test that checks for elevated levels of the chemicals hexanoylglycine and phenylpropionylglycine.

Prenatal testing for MCAD deficiency is available using a test similar to the PCR/FRET blood test. In this case, the DNA to be studied is extracted from the amniotic fluid rather than from blood. Another prenatal test involves studying the ability of cultured amniotic cells to breakdown added octanoate, an 8-carbon molecule that requires MCAD to break it down.

Because MCAD deficiency is generally treatable if it is recognized prior to the onset of symptoms, most parents of a potentially affected child choose to wait until birth to have their children tested.

Treatment and management

Because individuals affected with MCAD deficiency can still break down short-chain and long-chain fatty acids at a normal rate and most have a diminished, but functional, ability to break down medium-chain fatty

KEY TERMS

Apnea—An irregular breathing pattern characterized by abnormally long periods of the complete cessation of breathing.

Carnitine—An amino acid necessary for metabolism of the long-chain fatty acid portion of lipids. Also called vitamin B7.

Enzyme efficiency—The rate at which an enzyme can perform the chemical transformation it is expected to accomplish. This is also called turnover rate.

Founder effect—Increased frequency of a gene mutation in a population that was founded by a small ancestral group of people, at least one of whom was a carrier of the gene mutation.

Hepatomegaly—An abnormally large liver.

Hyperammonemia—An excess of ammonia in the blood.

Hypoglycemia—An abnormally low glucose (blood sugar) concentration in the blood.

Medium-chain acyl-CoA dehydrogenase—Abbreviated MCAD, the enzyme responsible for the breakdown of medium chain fatty acids in humans. People affected with MCAD deficiency produce a form of MCAD that is not as efficient as the normal form of MCAD.

Medium-chain fatty acids—Fatty acids containing between 4 and 14 carbon atoms.

acids, a precipitating condition must be present in order for symptoms of MCAD deficiency to develop. The most common precipitators of MCAD deficiency symptoms are stress caused by fasting or by infection. At these times, the body requires a higher than normal breakdown of medium chain fatty acids. MCAD deficient individuals often cannot meet these increased metabolic demands.

The main treatments for MCAD deficiency are designed to control or avoid precipitating factors. Persons affected with MCAD deficiency should never fast for more than 10 to 12 hours and they should strictly adhere to a low-fat diet. Blood sugar monitoring should be undertaken to control episodes of hypoglycemia. During acute episodes, it is usually necessary to administer glucose and supplement the diet with carbohydrates and high calorie supplements.

Many individuals affected with MCAD deficiency benefit from daily doses of vitamin B7 (L-carnitine). This

vitamin is responsible for transporting long chain fatty acids across the inner mitochondrial membrane. Elevated levels of L-carnitine ensure that these individuals break down long chain fatty acids in preference to medium chain fatty acids, which helps prevent acute symptomatic episodes of MCAD deficiency. Additionally, L-carnitine helps remove toxic wastes from the bloodstream to the urine, so it is also pivotal in controlling hyperammonemia.

Some individuals affected with MCAD deficiency present symptoms for the first time when they receive the diphtheria-pertussis-tetanus (DTP) vaccine. It is important that any person suspected to be affected with MCAD deficiency should receive treatment for hypoglycemia in connection with the administration of this vaccine. Chicken pox and middle ear infections (otitis media) have also been shown to initiate symptoms of MCAD deficiency.

Prognosis

MCAD deficiency has a mortality rate of 20%–25% during the first episode of symptoms. If an affected individual survives this first attack, the prognosis is excellent for this individual to have a normal quality of life as long as appropriate medical treatment is sought and followed.

McCune-Albright syndrome

Definition

McCune-Albright syndrome is a disorder characterized by abnormalities in bone development, skin pigmentation, and endocrine gland function.

Description

McCune-Albright syndrome (MAS) is an uncommon disorder in which a mutation distributed across various cell populations results in a wide variety of clinical features. The most notable features are abnormal bone development, pigmented skin spots, and endocrine gland dysfunction.

Genetic profile

McCune-Albright syndrome is not hereditary, but scientists have identified a specific genetic defect that causes MAS. The defect is a mutation in the *GNAS1* gene, which is associated with a type of G protein. These proteins are present in a wide variety of cells in the body. G proteins are part of the system of proteins and enzymes that regulate communication between cells and various agents such as hormones and the nervous system. If a cell's G protein is abnormal, this sets off a chain reaction that causes the cell to multiply inappropriately, and the subsequent cells produce too much hormone. The mutation first occurs in a single cell during the early stages of formation of the embryo. This cell multiplies into many other cells that eventually become part of the bones, skin, and endocrine glands. The severity of the syndrome is dependent on the percentage of cells involved. The earlier the mutation occurs, the more cells that will be affected. There is some evidence that a second mutation must occur before the clinical manifestations become evident.

Demographics

McCune-Albright syndrome is a rare genetic disorder with unknown incidence. It occurs equally in all races. Precocious puberty is far more common in affected girls than in boys, while other manifestations of the syndrome are believed to occur equally in both sexes. MAS has an estimated worldwide prevalence of between one in 100,000 and one in 1,000,000.

McCune-Albright: pedigree analysis chart (Gale)

Signs and symptoms

Three main features classically characterize McCune-Albright syndrome.

Abnormal bone development

Pockets of abnormal fibrous tissue develop within the bone, which may cause deformity, fractures, and nerve entrapment. Most of these lesions appear during the first decade of life. The pelvis and femur, or thighbone, are the most commonly involved areas of the skeleton. Bony abnormalities in the skull can cause blindness or deafness. The majority of patients with MAS have many of these lesions, hence the name polyostotic fibrous dysplasia.

In addition to these fibrous lesions, some patients develop osteosarcoma, which is a malignant tumor of the bone. Although it has not been proven, these tumors may originate from the fibrous lesions within the bone.

Pigmented skin spots

Patients with MAS typically have pigmented skin lesions called *café au lait* spots. These are flat areas of discoloration of the skin that may be associated with a variety of conditions. Those that are found in MAS have irregular borders. They are located on one side of the body, usually on the buttocks or lower back. Sometimes these lesions are present at birth.

Endocrine gland dysfunction

McCune-Albright syndrome is striking for its association with a number of endocrine abnormalities. Endocrine glands are those that secrete hormones directly into the bloodstream to be transported to other tissues of the

body. In MAS, one or more of these glands secrete abnormally high amounts of hormone.

The most common endocrine abnormality in MAS is excessive function of the gonads, which are ovaries in females and testicles in males. The ovaries secrete estrogen, and the testicles secrete testosterone. When these organs secrete too much estrogen or testosterone in children, the result is early puberty. Females are more commonly affected than males. In fact, early puberty in a girl is the hallmark sign of MAS. Typically, these girls develop secondary sexual characteristics, such as breasts and pubic hair, before the age of nine. Menses also begins early. Sometimes the normal sequence of development is disrupted, in that affected girls might have menses before breast or pubic hair development.

Hyperfunction of the pituitary gland also occurs in MAS, resulting in excess production of growth hormone and/or prolactin. Excess growth hormone leads to acromegaly, or marked overgrowth of certain bones and tissues, especially in the face and extremities. Some people with acromegaly grow to very tall stature. Acromegaly in MAS affects boys and girls equally. If too much prolactin is produced, then breast tissue will secrete milk inappropriately, in both boys and girls. This is called galactorrhea. In some patients, the pituitary gland dysfunction is caused by a tumor.

Other endocrine glands that may be hyperactive are the thyroid and adrenal glands. The thyroid gland produces thyroid hormones, which help regulate the body's metabolism. If excess thyroid hormones are produced, i.e., hyperthyroidism, then patients may have diarrhea, weight loss, nervousness, tremor, and rapid heartbeat. In

KEY TERMS

Dysplasia—The abnormal growth or development of a tissue or organ.

Pituitary gland—A small gland at the base of the brain responsible for releasing many hormones, including luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

some patients, thyroid nodules cause hyperthyroidism. The adrenal gland produces several hormones in the steroid hormone class, such as cortisol, aldosterone, and testosterone. Cortisol is most commonly over-produced. Similar to the pituitary gland, hyperfunction of the adrenal gland in MAS is sometimes caused by tumors.

Another feature of McCune-Albright syndrome is phosphate deficiency caused by excess excretion of phosphate in the urine. Since phosphate is a vital mineral for bone formation, this results in soft bones and some degree of pain. This condition is called rickets in children, and osteomalacia in adults. There are two theories that have been proposed to explain the loss of phosphate in the urine. First of all, it is thought that the fibrous bone lesions may produce an agent that circulates through the blood stream to the kidneys that makes the kidneys unable to retain phosphate. Secondly, perhaps the kidneys are intrinsically unable to retain the appropriate amount of phosphate.

It is important to emphasize the variability of clinical features among patients with MAS. Not every patient has the three features of bony lesions, pigmented skin spots, and endocrine abnormalities. Each patient is affected uniquely. There are rare subtypes of the syndrome in which patients have hepatitis, cardiac arrhythmias, or intestinal polyps.

Gastrointestinal issues

MAS may be associated with a broad spectrum of gastrointestinal (GI) diseases. Neonatal cholestasis and hepatitis have been reported in infants, and a variety of hepatobiliary abnormalities have been reported in adults, including hepatocellular adenomas, choledochal cysts, and inflammatory adenomas. However, the clinical spectrum and prevalence of MAS-associated GI disease are not well established. Gastric polyps may be asymptomatic or associated with symptoms of reflux. Activating GNAS mutations are known drivers for the development of intraductal papillary mucinous neoplasms (IPMNs). These pancreatic cysts have been reported in up to 40% of patients with MAS and have rarely been associated

with obstructive pancreatitis and diabetes. Gastrointestinal evaluation, including pancreatic imaging, should therefore be considered in all symptomatic patients.

One study described the clinical and radiographic GI abnormalities associated with MAS. The results of the study revealed that GI manifestations in MAS are common, and that patients with MAS may benefit from being evaluated for GI pathology. When compared with screened patients without GI disease, those with MAS-linked GI pathology had an increased frequency of acute pancreatitis, diabetes mellitus, and fibrous dysplasia. The optimal care for GI findings in MAS remains to be defined, but at the minimum, a thorough GI history at every visit and consideration of imaging with abdominal magnetic resonance imaging (MRI)/magnetic resonance cholangiopancreatography (MRCP) are warranted.

Diagnosis

There is no single test that is diagnostic for MAS. Certain clinical features can be easily observed, such as skin pigmentation and early puberty. X-ray can confirm the bony abnormalities. Blood tests for hormone levels can detect endocrine gland dysfunction.

Treatment and management

There is no specific treatment that cures the disease. Testalactone and fadrozole are drugs that inhibit estrogen production and have been successful in the short-term treatment of girls with early puberty, but long-term treatment has not been very effective. Patients with pituitary tumors may benefit from drugs to reduce tumor size, or surgery to remove the tumors. Thyroid nodules can be treated by surgical removal or destruction with radioactive iodine. Thyroid-inhibiting medications such as propylthiouracil and methimazole are also used for the treatment of MAS. In addition, adrenal tumors can be removed by surgery, and bone grafting, pinning, and casting are techniques used in the treatment of MAS.

Clinical trials

The National Institutes of Health (NIH) and other agencies sponsor clinical trials on MAS and related conditions.

Examples include:

- The evaluation of the effectiveness of Arimidex in the treatment of precocious puberty in girls with MAS. (NCT00055302)
- A study to determine the efficacy of Fulvestrant in the treatment of precocious puberty in girls with MAS. (NCT00278915).

QUESTIONS TO ASK YOUR DOCTOR

- What is McCune-Albright Syndrome (MAS)?
- What treatments are available for the symptoms I am suffering?
- What are the costs and potential side effects of these treatment options?
- What bones are most affected by MAS?
- What screening options are available to me if I have MAS, and I wish to have children?

- Screening and natural history of patients with polyostotic fibrous dysplasia and McCune-Albright Syndrome. (NCT00001727).

NIH constantly updates clinical trial information, and the most recent information on MAS trials can be found at: <http://www.clinicaltrials.gov>

Prognosis

The lifespan in patients with McCune-Albright syndrome is essentially normal. Women who experienced early puberty as girls are generally fertile.

McCusick-Kaufman syndrome

Definition

McCusick-Kaufman syndrome (MKS) is a developmental disorder characterized by a group of conditions that includes congenital heart disease, buildup of fluid in the female reproductive tract, and extra toes and fingers.

Description

McKusick reported the first case of a disorder which he called hydrometrocolpos syndrome in 1964. Shortly thereafter, Kaufman described another individual with a very similar group of abnormalities. Subsequent writers combined these syndromes into one, calling it McKusick-Kaufman syndrome and characterizing its wide range of features.

MKS is the first human disorder to be attributed to a mutation occurring in a gene and affecting a type of molecule called a chaperonin. Chaperonins are sometimes called “protein cages” in that they protect cells by capturing and refolding misshapen proteins that could otherwise interfere with normal cellular functions.

Genetic profile

MKS is inherited in an autosomal recessive pattern, meaning that a child must inherit two altered genes, one from each parent, to be affected. An altered gene responsible for a rare developmental syndrome found predominantly among the Old Order Amish population has been identified. Mutations in the gene responsible for MKS have been identified on chromosome 20p12 in an Amish family. Scientists have isolated the McKusick-Kaufman syndrome gene by positional cloning.

Based on an earlier genetic analysis of the Old Order Amish population, a research group looked at a region of chromosome 20 thought to contain the gene responsible for the syndrome. A technique called sample sequencing was then used to find candidate genes in that region. One of those genes, dubbed *MKS*, was altered in a sample from an Amish person as well as in a sample from a non-Amish person diagnosed with MKS. In both people, errors or “misspellings” in the genetic code were found that would disturb the function of the *MKS* gene. It was observed that the chemical building blocks (amino acids) coded by the *MKS* gene appeared to be very similar to those that make up the chaperonins. Although the function of the protein made by the *MKS* gene is unclear, it appears to be involved in the production of proteins associated with the development of limbs, the heart, and the reproductive system.

In 2000, researchers identified a gene mutation that causes Bardet-Biedel syndrome (BBS), a rare genetic disorder that is related to MKS. BBS is believed to be due to a complete absence of the gene responsible for MKS.

Demographics

Between 1% and 3% of the Amish people of Lancaster County, Pennsylvania, are believed to be carriers of the disease, having just one copy of the altered gene.

KEY TERMS

Atresia—An abnormal condition in which a structure that should be hollow is fused shut.

Chaperonin—A molecule that captures and refolds misshapen proteins that might interfere with normal cellular functions; also called a protein cage.

Choanal atresia—A bony or membranous blockage of the passageway between the nose and pharynx at birth.

Cryptorchidism—A condition in which one or both testes fail to descend normally.

Dysplasia—The abnormal growth or development of a tissue or organ.

Genome—A term used to describe a complete representation of all of the genes in a species.

Hydrometrocolpos—An abnormal accumulation of fluids in the uterus and vagina.

Hydrops fetalis—A condition characterized by massive edema in a fetus or newborn.

Hypospadias—An abnormality of the penis in which the urethral opening is located on the underside of the penis rather than at its tip.

Polydactyly—The presence of extra fingers or toes.

Positional cloning—Cloning a gene simply on the basis of its position in the genome, without having any idea of the function of the gene.

Tracheo-esophageal fistula—Abnormal connection between the trachea and esophagus, frequently associated with the esophagus ending in a blind pouch.

The related Bardet-Biedel syndrome is estimated to occur between 1 in 125,000 and 1 in 160,000 people. Among an isolated community in Newfoundland, Canada, the prevalence is estimated to be ten times higher.

Signs and symptoms

Many abnormalities associated with MKS are visible in a physical exam. They include the following abnormalities:

- Limbs: polydactyly (extra fingers or toes)
- Genitourinary system in females: hydrometrocolpos (accumulation of fluids in the uterus and vagina), transverse vaginal membrane, vaginal atresia (absence of a vagina)
- Genitourinary system in males: hypospadias (abnormal opening of the urinary tract), prominent scrotal raphe

(ridges), micropenis, cryptorchidism (undescended testicles)

- Cardiac: congenital heart defects
- Head: pituitary dysplasia (abnormal development of the pituitary gland), choanal atresia (bony or membranous blockage of the passageway between the nose and pharynx), retinitis pigmentosa (overactive cells in the retina of the eye leading to blindness), tracheo-esophageal fistula (abnormal passage in the throat region)
- Skeleton: vertebral anomalies
- Abdomen: distension, peritoneal cysts, Hirschsprung megacolon (enlarged and poorly functioning large intestine)
- Other: nonimmune hydrops fetalis (massive build-up of fluids in a fetus or newborn)

Diagnosis

A diagnosis of McKusick-Kaufman syndrome is usually made at birth when a newborn is given a post-natal physical exam. The diagnosis is made by noting physical abnormalities such as: polydactyly, hydrometrocolpos, a transverse vaginal membrane, vaginal atresia, hypospadias, prominent scrotal raphe, micropenis, cryptorchidism, congenital heart defects, pituitary dysplasia, choanal atresia, tracheo-esophageal fistula, vertebral anomalies, abdominal distension, peritoneal cysts, Hirschsprung megacolon, or nonimmune hydrops fetalis. The probability of a correct diagnosis increases with each additional abnormality present. A diagnosis may sometimes be confirmed with a chromosomal analysis. Abnormal development of the pituitary gland (pituitary dysplasia) and vertebral abnormalities are visible in a CT or MRI scan. Peritoneal cysts are commonly diagnosed by ultrasonography.

Treatment and management

Treatment of MKS is limited to surgical correction of defects. Timing is often important. Many abnormalities, if uncorrected, can quickly become life threatening. For example, hydrops fetalis is often fatal. Genetic counseling before marriage is recommended for persons who are possible carriers of MKS. Affected rural and Amish girls should be delivered in settings that allow rapid surgical intervention and correction of abnormalities. Such actions could be lifesaving.

Prognosis

With appropriate genetic counseling and complete family histories, individuals born with MKS can receive prompt treatment. With rapid initial surgical intervention, most of these persons can live relatively normal lives.

QUESTIONS TO ASK YOUR DOCTOR

- What is the genetic cause for McKusick-Kaufman syndrome?
- What are the most common symptoms of this disorder?
- How is McKusick-Kaufman syndrome diagnosed in an infant?
- What types of surgery are used to treat the symptoms of McKusick-Kaufman syndrome, and what risks are associated with each procedure?

Some abnormalities, such as hypospadias, vaginal atresia, choanal atresia, tracheo-esophageal fistula, or Hirschsprung megacolon, may require multiple operations. Due to the risk of retinitis pigmentosa, vision should be monitored closely.

Meckel syndrome see **Meckel-Gruber Syndrome**

Meckel-Gruber syndrome

Definition

Meckel-Gruber syndrome (MGS) is an inherited condition that causes skull abnormality, enlarged cystic kidneys, liver damage, and extra fingers and toes. Findings vary between affected infants (even in the same family), as well as between ethnic groups. Infants with MGS are usually stillborn or die shortly after birth.

Description

The first reports of MGS were published in 1822 by Johann Friedrich Meckel. G. B. Gruber also published reports of MGS patients in 1934 and gave it the name dysencephalia splanchnocystica. MGS is also known as Meckel syndrome and Gruber syndrome.

MGS affects many different organ systems including the central nervous system (brain and spinal cord), face, kidneys, liver, fingers and toes, and occasionally the bones of the arms and legs. Some researchers believe that abnormal development and differentiation of the embryonic mesoderm (the early tissue layer that contributes to the formation of the bones, cartilage, muscles, reproductive system, blood cells, heart, and kidneys) is related to MGS. The cells of the mesoderm must divide, migrate, associate, and specialize in a precise manner to form these body parts. A problem in any step of this process can lead to multiple abnormalities in various organ systems.

Since MGS causes severe birth defects and death in the newborn period, it can be devastating for families. Extensive examination and autopsy are often needed to confirm a diagnosis of MGS, delaying the family's answers regarding their child's death. Most parents do not know they are at risk until they have a child with MGS. This can cause feelings of anger, disbelief, and guilt.

This example of Meckel's diverticulum is the pouch (upper center) protruding from the wall of the small intestine. (CNRI/Science Source)

Genetic profile

The autosomal recessive inheritance pattern in MGS is well-documented. MGS affects males and females equally. Parents of affected children are assumed to be carriers and have a 25% chance of MGS recurrence in each pregnancy. A healthy brother or sister of an affected child has a two-thirds chance of being an MGS carrier.

Research involving families in Finland (where MGS is more common) led to the first MGS gene being mapped (localized) to the short arm of chromosome 17. This means that the gene location has been narrowed down to a small potential area, but the exact location and precise details about the gene are still unknown. Non-Finnish families did not show evidence of a causative gene linked to chromosome 17. This led to the search for a second MGS gene. Studies of Northern African and Middle Eastern families resulted in the second MGS gene being mapped to the short arm of chromosome 11. More research is being performed to learn more about the precise location of both MGS genes, gene changes that cause MGS, and the role of the genes in early development.

Demographics

MGS has an estimated incidence between 1 in 13,000 births and 1 in 140,000 births. This means that between 1 person per 50 and 1 person per 180 is an MGS carrier. The incidence varies among ethnic groups. Several ethnic populations have an increased incidence of MGS. The incidence in Finland is 1 in 9,000 births (1 person in 50 is a carrier). The incidence is also higher among Belgians and Bedouins in Kuwait with 1 affected birth in 3,500 (1 person in 30 is a carrier). The highest incidence is reported in the Gujarati Indians with 1 affected birth per 1,300 (1 person in 18 is a carrier). The incidence among Jews in Israel is 1 in 50,000 (1 person in 112 is a carrier). Cases of MGS have been reported in North America, Europe, Israel, Indonesia, India, Kuwait, and Japan.

Signs and symptoms

The three hallmark features of MGS are encephalocele, polycystic kidneys, and polydactyly. Approximately 90% of infants with MGS have an encephalocele. This is an opening in the skull that allows brain tissue to grow outside of the skull. Nearly 100% of infants with MGS have enlarged kidneys with cysts. Polydactyly (extra fingers and/or toes) is present in about 80% of affected children. The polydactyly is usually postaxial (the extra fingers/toes are on the same side of the hand/foot as the smallest finger/toe). In MGS, the polydactyly usually affects both the hands and feet. There may also be webbing of the fingers and toes—the skin between the fingers

KEY TERMS

Bile duct—A passageway that carries bile (fluid secreted by the liver involved in fat absorption) from the liver to the gallbladder to the small intestine.

Clubfoot—Abnormal permanent bending of the ankle and foot. Also called *talipes equinovarus*.

Trimester—A three-month period. Human pregnancies are normally divided into three trimesters: first (conception to week 12), second (week 13 to week 24), and third (week 25 until delivery).

or toes fails to separate—leaving the digits attached to each other.

Internal examination of babies with MGS revealed that virtually 100% have liver abnormalities. This can include halted development of the bile ducts, extra bile ducts, enlarged bile ducts, and loss of blood vessels. The liver is also usually enlarged. These liver changes are now considered by most to be another hallmark feature of MGS.

Babies with MGS often have similar facial features. Some reported features are eyes that are closer together or farther apart than usual, broad and flat nose, broad cheeks, and a wide mouth with full lips. Other features are commonly seen in MGS and are thought to be caused by a low amount of amniotic fluid surrounding the baby before birth. These features are sloping forehead, small jaw, low-set ears, and short, webbed neck. Low fluid prior to birth also frequently causes clubfoot in the newborn.

Other common features of MGS are abnormalities of the genitalia and cleft palate. The external (visible) genitalia are often small or ambiguous (not clearly male or female). There have also been reports of babies with MGS having both male and female reproductive parts (hermaphrodite). Cleft palate is seen in about 45% of babies with MGS. Cleft lip is less common but has been reported.

The symptoms of MGS are variable. Not all infants with MGS show the same signs, and the characteristic signs range in severity. Some features have been described in some babies with MGS but are not as common. These include heart defects, enlarged spleen, extra spleen, hydrocephaly (extra water in the brain), absence or underdevelopment of other brain structures, and arm and leg bones that are shortened, thickened, and bowed.

QUESTIONS TO ASK YOUR DOCTOR

- How early in a pregnancy can Meckel-Gruber syndrome be diagnosed, and how is that diagnosis made?
- What information can a genetic counselor provide my spouse and me about this genetic disorder?
- Are there treatments available that will prolong the life of a child with Meckel-Gruber syndrome and/or make the child's life more comfortable?
- What is the status of current research on Meckel-Gruber syndrome?

Diagnosis

Some of the features of MGS can be detected by prenatal ultrasound early in the second trimester. At that time, an encephalocele can often be seen as well as other brain abnormalities. Enlarged kidneys can also be detected at this time. As the pregnancy continues, a low amount of amniotic fluid becomes apparent. Enlarged kidneys make the abdomen appear and measure larger than usual. Cysts make the kidneys appear bright or white on an ultrasound instead of the usual gray color.

Measurement of the alpha-fetoprotein (AFP) level from either maternal blood or amniotic fluid may help to detect an encephalocele (although most encephaloceles are closed and do not elevate AFP levels). AFP can be measured in amniotic fluid after about 12 weeks of pregnancy and in maternal blood after about 15 weeks of pregnancy. AFP elevation in either test increases the chance of an encephalocele or other abnormality in the baby's skull or spine.

When signs of MGS are seen on prenatal ultrasound in the absence of a family history, MGS is often suspected but not confirmed until after birth and autopsy. A chromosome test can be performed before birth to rule out chromosome abnormalities such as trisomy 13. However, autopsy is usually needed to distinguish MGS from other syndromes with similar features. Every organ system of the baby is carefully examined for abnormal development.

Families at risk for recurrence of MGS can combine early ultrasound with either maternal blood AFP or amniotic fluid AFP for early detection. If early ultrasound reveals no signs of MGS, later scans are still recommended

because of the variability in expression and severity. No routine genetic tests are available to these families.

Treatment and management

There is no effective treatment or cure for MGS. Babies with MGS have extensive birth defects that require many surgeries to repair. Encephaloceles can be repaired by surgery after birth. Surgeries are most successful for infants with small skull abnormalities. Encephaloceles put infants at high risk for infection. The abnormalities seen in the kidneys and liver often leave the organs nonfunctional. There is often no way to repair the organs other than transplant. Even if all of these problems could be solved, infants with MGS often have underdeveloped lungs that cannot support life after birth. The lungs are underdeveloped because of the low amount of amniotic fluid prior to birth. Due to the extensive birth defects, the extensive surgeries needed to correct them, and the poor prognosis, babies born with MGS are given minimum care for comfort and warmth.

When MGS is suspected in an unborn baby, parents should be given information about the range of symptoms of MGS and the poor prognosis. Parents should also be cautioned that a diagnosis of MGS often cannot be confirmed until after birth. Prognosis can vary if the baby has atypical signs of MGS or if the baby has a different syndrome. Elective termination of affected pregnancies may be an option for some couples.

Prognosis

The prognosis for MGS is quite poor. Many infants with MGS are stillborn. Those that are born alive usually die shortly after birth in the first hours, days, or weeks of life. Death is usually due to inability to breathe (underdeveloped lungs), infection (opening in the skull), or organ failure (decreased function of kidneys and liver). MGS is variable, and there have been reports of infants with milder symptoms living longer. One infant with MGS lived until four months of age. Another lived to seven months of age after surgical repair of a small encephalocele. At birth he had cystic kidneys but normal kidney function. These two case reports show that longer survival is rare but possible because of the variable expression of MGS.

Meckel's diverticulum

Definition

Meckel's diverticulum is a congenital pouch (diverticulum) approximately 2 in. (4 cm) in length and located at the lower (distal) end of the small intestine. It was named for Johann F. Meckel, a German anatomist who first described the structure.

Description

The diverticulum is best described as a blind pouch that is a remnant of the omphalomesenteric duct or yolk sac that nourished the early embryo. It contains all layers of the intestine and may have ectopic tissue present from either the pancreas or stomach.

The rule of twos is the classical description. It is located about two feet from the end of the small intestine, is often about two inches in length, occurs in about 2% of the population, is twice as common in males as females, and can contain two types of ectopic tissue—stomach or pancreas. Many people who have a Meckel's diverticulum never have trouble, but those that do present in the first two decades of life, and often in the first two years.

There are three major complications that may result from the development of Meckel's diverticulum. The most common problem is inflammation or infection that mimics appendicitis. This diagnosis is defined at the time of surgery for suspected appendicitis. Bleeding caused by ectopic stomach tissue that results in a bleeding ulcer is the second most frequent problem. Bleeding may be brisk or massive. The third potential complication is obstruction due to intussusception, or a twist around a persistent connection to the abdominal wall. This problem presents as a small bowel obstruction.

However, the true cause is identified at the time of surgical exploration.

Genetic profile

Meckel's diverticulum is not hereditary. It is a vestigial remnant of the omphalomesenteric duct, an embryonic structure that becomes the intestine. As such, there is no genetic defect or abnormality.

Demographics

Meckel's diverticulum is a developmental abnormality that is present in about 2% of people, but does not always cause symptoms. Meckel's diverticula (plural of diverticulum) are found twice as frequently in men as in women. Complications occur three to five times more frequently in males.

Signs and symptoms

Symptoms usually occur in children under ten years of age. There may be bleeding from the rectum, pain and vomiting, or simply tiredness and weakness from unnoticed blood loss. It is common for a Meckel's diverticulum to be mistaken for the much more common condition appendicitis. If there is obstruction, the abdomen will distend and there will be cramping pain and vomiting.

Diagnosis

The situation may be so acute that surgery is needed on an emergency basis. This is often the case with bowel obstruction. With heavy bleeding or severe pain—whatever the cause—surgery is required. The finer points of diagnosis can be accomplished when the abdomen is open for inspection during a surgical procedure. This situation is called an acute abdomen.

If there is more time (not an emergency situation), the best way to diagnose Meckel's diverticulum is with a nuclear scan. A radioactive isotope injected into the bloodstream accumulates at sites of bleeding or in stomach tissue. If a piece of stomach tissue or a pool of blood shows up in the lower intestine, Meckel's diverticulum is indicated.

Treatment and management

A Meckel's diverticulum that is causing discomfort, bleeding, or obstruction must be surgically removed. This procedure is very similar to an appendectomy.

Prognosis

The outcome after surgery is usually excellent. The source of bleeding, pain, or obstruction is removed, so

KEY TERMS

Appendectomy—The procedure to surgically remove an appendix.

Appendicitis—Inflammation of the appendix.

Appendix—A portion of intestine attached to the cecum.

Catecholamines—Biologically active compounds involved in the regulation of the nervous and cardiovascular systems, rate of metabolism, body temperature, and smooth muscle.

Cecum—The first part of the large bowel.

Congenital—Refers to a disorder that is present at birth.

Connective tissue—A group of tissues responsible for support throughout the body; includes cartilage, bone, fat, tissue underlying skin, and tissues that support organs, blood vessels, and nerves throughout the body.

Distal—Away from the point of origin.

Diverticulae—Sacs or pouches in the walls of a canal or organ. They do not normally occur, but may be acquired or present from birth. Plural form of diverticula.

Ectopic—Tissue found in an abnormal location.

Enzyme—A protein that catalyzes a biochemical reaction or change without changing its own structure or function.

Intussusception—One piece of bowel inside another, causing obstruction.

Isotope—Any of two or more species of atoms of a chemical element with the same atomic number and nearly identical chemical behavior but with differing atomic mass and physical properties.

Jaundice—Yellowing of the skin or eyes due to excess of bilirubin in the blood.

Linkage analysis—A method of finding mutations based on their proximity to previously identified genetic landmarks.

Peptic ulcer—A wound in the bowel that can be caused by stomach acid or a bacterium called *Helicobacter pylori*.

Tortuous—Having many twists or turns.

Volvulus—A twisted loop of bowel causing an obstruction.

the symptoms also disappear. A Meckel's diverticulum will not return.

Melanoma

Definition

Melanoma is a type of cancer most often found in the skin, but occasionally in the eye, throat, or intestines. Its name is derived from the Greek word for black. Melanocytes, the pigmented cells that produce a brownish-black pigment known as melanin and are responsible for racial variations in skin color, the color of moles, and tanning in response to sun exposure, are the cells that give rise to melanoma. In malignant melanoma, the melanocytes become cancerous and may spread throughout the body to invade other organs and tissues.

Demographics

Melanoma accounts for only 4% of skin cancers in the United States; however, it is responsible for 75% of deaths from skin cancer. According to the National Cancer Institute (NCI), 106,110 new cases of melanoma will be diagnosed in the United States in 2021 (about 62,260 cases in men, and 43,850 in women), or about 5.6% of all cancers; and 7,180 people will die from the disease (4,600 men, and 2,580 women), or about 1.2% of all cancer deaths. There are about 500 cases of melanoma diagnosed in children each year in the United States. Melanoma was considered a rare form of cancer until the 1970s, but its rate among Caucasians in the United States has tripled since 1985. Unlike many cancers, which are declining in incidence as of 2021, the incidence of primary cutaneous malignant melanoma has been steadily increasing since 1980, possibly related to increased sun exposure and the popularity of tanning salons. Currently, the risk is about 22.8 per 100,000 people in the general American population.

Melanoma affects all age groups but is most commonly seen in adult patients; the average age at the time of diagnosis is 65 as of 2021. Nonetheless, the rate of melanoma is rising more rapidly among young people than among older adults; melanoma is now the most common cancer diagnosed in young adults between the ages of 25 and 29. The current overall lifetime risk of melanoma in the United States is about 2.6% (one person in 38) for Caucasians; 0.1% (one in 1,000) for African Americans; and 0.6% (one in 167) for Hispanics/Latinos.

One of the more unusual findings in the United States in recent years is the rapid increase of deaths from melanoma in older males. Although the death rate among younger men (age 44 or younger) has dropped since the late 1990s, most likely as a result of public health education campaigns about the dangers of sun exposure, it has risen 66% in men between the ages of 45 and 64, and 157% in men over 65. By age 80, American men are three times as likely to die of melanoma as are women of the same age.

According to the Melanoma Network of Canada, melanoma is the seventh most commonly diagnosed cancer in Canada. The network estimates that 8,200 Canadians (4,500 men, and 3,700 women) will be diagnosed with melanoma in 2021, and that 1,300 (870 men and 430 women) will die from this form of cancer.

The highest rates of melanoma in the world, however, are not found in the United States or Canada but in Australia and New Zealand. According to Melanoma Institute Australia, melanoma could be called Australia's national cancer. In 2021, the institute estimates that 16,000 Australians will be diagnosed with melanoma, and 1,300 will die from it. It is the single most common cancer in Australians between the ages of 15 and 39.

Description

The epidermis, the uppermost layer of skin, contains melanocytes, the cells that make melanin, which is the pigment that gives skin its hue. Melanin is responsible for the color of a person's skin, hair, and eyes. There are between 1,000 and 2,000 melanocytes in each square millimeter of human skin. The difference in skin color between fair-skinned and darker-skinned people is not based on the number of melanocytes in the skin but on their level of activity. When skin is exposed to the sun, the melanocytes become more active, produce more melanin, and cause the skin to darken—that is, they cause a suntan. When a cancerous tumor develops in tissue containing melanocytes, a person is said to have melanoma.

Most cases of melanoma occur in the skin (cutaneous melanoma), but sometimes melanoma can also occur in the colored layer of eye tissue—a condition known as intraocular or uveal melanoma.

Cutaneous melanoma

Between 70% and 80% of cutaneous melanomas arise from normal skin; the remaining 20% to 30% develop in moles (also called nevi). Moles are benign growths or collections of melanocytes on the skin surface. According to the American Academy of Dermatology, most individuals have about 30 moles on their skin. The number and type of moles that individuals have may increase the risk of melanoma. People with more than 50 moles or with moles that are unusual and irregular-looking (doctors call these dysplastic nevi or atypical moles) are at increased risk of developing melanoma.

There are four major types of cutaneous (skin-based) melanoma:

- Superficial spreading melanoma accounts for 70% of all cases of melanoma and typically occurs in younger people. This type of melanoma takes a long time to penetrate the top layer of skin, and the first sign of it is a

Melanoma, a type of skin cancer that develops in melanocytes, creating asymmetrical moles with irregular borders and discoloration. Melanocytes produce melanin, the pigment that gives color to the skin. Prolonged exposure to ultraviolet (UV) light can damage melanocyte DNA, causing cells to replicate out of control and even spread to other parts of the body. (Evan Oto/ Science Source)

flat or slightly raised skin lesion. The lesion may be discolored with irregular borders and may develop out of a previously benign mole. It is most likely to occur on the trunk in men, the legs in women, and the upper back in men and women.

- Lentigo maligna is another form of melanoma that is most often found in older adults. It begins as a flat or slightly raised tan, brown, or dark brown skin discoloration that remains close to the skin's surface. Once the malignancy spreads, it is referred to as lentigo maligna melanoma. It accounts for 5% to 10% of melanoma cases.
- Acral lentiginous melanoma is the most common type of melanoma in African Americans and Asians, and is least common among Caucasians. It accounts for 7% to 10% of melanomas. The black or brown discoloration of acral lentiginous melanoma first spreads along the surface of the skin, often under the nails or on the soles of the feet or palms of the hands.
- Nodular melanoma, which accounts for 15% to 20% of all melanoma cases, is the most aggressive form of melanoma, and by the time it is diagnosed, it may have spread to other areas of the body. This type of melanoma

starts as a lump that is usually black in color. Nodular melanoma is found most frequently on the trunk, legs, and arms, and most often affects older people.

Superficial spreading melanoma, lentigo maligna melanoma, and acral lentiginous melanoma begin as in situ malignancies, which means they affect only the top layers of skin. Eventually, these forms of melanomas may become invasive and spread to other areas of the body. Nodular melanoma is often invasive by the time it is diagnosed, however.

Intraocular (uveal) melanoma

Intraocular melanoma, or melanoma within the eye, is a cancer that develops in the parts of the eye that contain melanocytes—the iris and other nearby structures that belong to the uvea, the middle pigmented layer of the eye. About 5% of uveal melanomas develop in the iris, with the majority being found in the posterior uvea. Melanomas in the iris usually involve mutations in the *BRAF* gene, while melanomas in the posterior uvea are more often caused by *GNAC/GNA11* mutations. There are about 2,500 cases of

KEY TERMS

Adjuvant therapy—Treatment given to patients who are at risk of having microscopic untreated disease present but have no obvious symptoms.

Breslow depth—A measurement of the thickness of a cutaneous melanoma, used in staging the cancer. It is named for Alexander Breslow, an American pathologist who first identified it as a prognostic factor for melanoma in 1970.

Cutaneous—Pertaining to or affecting the skin. Most melanomas are cutaneous cancers.

Dendritic cells (DCs)—Accessory cells in the mammalian immune system that acts as messengers between the adaptive and innate immune systems. Their name is derived from their tree-like shape.

Electrodessication—A surgical technique for removing skin cancers by drying out tissue with an electric current and then removing the dead tissue with a curette.

Fitzpatrick phototype scale—A set of six skin types based on the skin's response to the ultraviolet radiation in sunlight. The scale was devised in 1975 by Thomas Fitzpatrick, a dermatologist at Harvard University. Fitzpatrick types I and II are at the greatest risk of melanoma.

Genome—The total amount of genetic information within an organism's chromosomes, including its genes and DNA sequences.

Immunotherapy—A form of treatment that uses biologic agents to enhance or stimulate normal immune function.

Melanocytes—Skin cells derived from the neural crest that produce the protein pigment melanin.

Metastasis (plural, metastases)—A tumor growth or deposit that has spread via lymph or blood to an area of the body remote from the primary tumor.

Mohs surgery—A form of microscopically controlled surgery that allows for the precise removal of cancerous tissue. It is commonly used to treat various types of skin cancer, particularly in areas of the body where preserving as much tissue as possible is essential. Mohs surgery is also known as micrographic surgery.

Nevus (plural, nevi)—The medical term for mole; it is derived from the Latin word for birthmark.

Oncogene—A gene that has the potential to cause cancer.

Oncology—The branch of medicine concerned with the study, diagnosis, treatment, and prevention of cancer.

Resection—The act of removing an organ or tissue surgically.

Spitz nevus—A benign reddish or reddish-brown skin lesion that is difficult to distinguish from melanoma and is usually removed for that reason. Spitz nevi are named for Sophie Spitz, an American pathologist who first described them in 1948.

Targeted therapy—In cancer treatment, a type of drug therapy that blocks tumors by interfering with signaling pathways or specific molecules that the cancer cells need for growth. Also called biologic therapy, targeted therapy is less harmful to normal cells than traditional chemotherapy.

Uvea—The medical term for the pigmented middle layer of the three layers of tissue comprising the eye. The uvea includes the iris, the ciliary body, and the choroid. Melanomas that develop in these structures are called uveal melanomas.

Xeroderma pigmentosum (XP)—A rare inherited skin disorder in which the skin cells lack an enzyme needed to repair damage to the cell's DNA caused by sunlight. People with XP are 1,000 times more likely to develop melanoma than people without the disorder.

intraocular melanoma diagnosed per year in the United States; it is most likely to develop in people with blue eyes and fair skin. Uveal melanoma is more common in Denmark and other Scandinavian countries than in the United States. It is slightly more common in men than in women. The average age of a person diagnosed with this type of melanoma is 55.

Intraocular or uveal melanomas can grow slowly for years without producing any symptoms, although they eventually cause blurred vision, seeing double, a sensation

of having a foreign body in the eye, gradual loss of sight, and sometimes pain in the eye. This type of melanoma often spreads from the eye to the liver, the lungs, or even the central nervous system before it is diagnosed. Most patients die from the spread of the cancer to these vital organs rather than from the effects of the cancer on the eye itself. About half of all patients diagnosed with intraocular melanoma die within 10 years after diagnosis and treatment. The standard forms of treatment for this type of cancer are radiation therapy and surgical removal of the affected eye.

Risk factors

Malignant melanoma occurs in people of all ages and ethnicities. However, certain factors put people at greater risk of developing this disease:

- Belonging to Fitzpatrick phototypes I and II: people who have fair skin; red or blond hair; and blue or green eyes. The Fitzpatrick phototypes are a set of six skin types based on the skin's response to the UV radiation in sunlight. The scale was devised by an American dermatologist in 1975.
- Being older than age 20; the rate of melanoma rises sharply after age 50.
- History of excessive sun exposure, exposure to artificial ultraviolet light (such as in tanning beds), or a history of severe (blistering) sunburns in childhood.
- Living in areas that get high levels of ultraviolet radiation, such as mountainous regions or countries closer to the Equator.
- Having a previous personal history of melanoma or another type of skin cancer.
- Having extensive scars or burns on the skin. Fragile skin is more easily damaged by sun.
- Occupational exposure to certain chemicals in the environment, including arsenic and some types of weed killers.
- Having a job that requires working outdoors during daylight hours.
- Having a close relative with melanoma; about 20% of cases of melanoma are familial.
- Having a high number of moles (50 or more).
- Having moles that are unusual in appearance or irregular in shape.

Having certain procedures or health conditions that weaken the immune system may also predispose a person to developing melanoma. Compared to people in the general population, those who have undergone organ transplants have a threefold risk of melanoma. Having human immunodeficiency virus (HIV) or acquired immunodeficiency syndrome (AIDS), other forms of cancer, or autoimmune diseases that require immunosuppressive treatments can also increase a person's risk of developing malignant melanoma.

A rare inherited condition known as xeroderma pigmentosum (XP) increases a person's risk of malignant melanoma. People with XP lack an enzyme that is needed to repair damage caused by sunlight to the DNA in skin cells. Without this protective enzyme, the DNA in individual skin cells can undergo mutations leading to melanoma and other types of skin cancer. XP is inherited in an autosomal recessive manner; it can be caused by

mutations in any of nine genes (*DDB2*, *ERCC1*, *ERCC2*, *ERCC3*, *ERCC4*, *ERCC5*, *POLH*, *XPA*, or *XPC*). The average life expectancy of a person with XP is 37 years.

Causes and symptoms

Causes

ULTRAVIOLET RADIATION. The development of melanomas from normal skin is not completely understood. As of 2021, researchers think there may be two pathways to malignant melanoma, one involving exposure to sunlight and the other with melanocyte proliferation triggered by other factors. This hypothesis is based on the difference in distribution of moles on the body between patients who develop melanomas on the face and neck, and those who develop melanomas on the trunk or legs. A small percentage of melanomas arise within burn scar tissue. Researchers do not fully understand the relationship between deep burns and an increased risk of skin cancer. In general, however, melanoma is caused by the interaction of ultraviolet (UV) radiation from the sun and the melanin in melanocytes. UV radiation can damage the DNA in skin cells both directly and indirectly. Researchers have found that 92% of melanomas are caused by indirect damage to DNA, and 8% by direct damage.

When the DNA in a skin cell is damaged by UV radiation, the cell can undergo a series of mutations that lead to abnormal multiplication of new cells. In some cases, the changed DNA makes the cell more vulnerable to the damaging effects of UV radiation.

Melanomas grow in two stages or phases. The first is a phase of outward or radial growth. The second phase, which is much more dangerous, is a phase of vertical growth into deeper layers of tissue. It is during this second phase of growth that melanomas become harder to treat and more likely to spread to other parts of the body.

ENVIRONMENTAL CHANGES. Melanoma was a rare form of cancer until the twentieth century. The earliest known surgical removal of a melanoma was performed in 1787 by a British surgeon, but the disease was little studied until the 1840s and 1850s, when two other British doctors described the stages of melanoma and found that it runs in some families. The connection between melanoma and sun exposure was not made until 1956, when an Australian doctor named Henry Lancaster found that the high intensity of sunlight is a risk factor for melanoma. In the 1970s, scientists began to notice that the ozone layer—a layer of oxygen molecules consisting of three atoms of oxygen in the upper atmosphere—was becoming thinner. The ozone layer helps to block a high-energy type of ultraviolet radiation known as UVB from reaching the surface of the earth, so doctors began

to wonder whether a thinner ozone layer contributed to an increased rate of skin cancers.

As of 2021, however, doctors do not think that the rise in cases of melanoma is due primarily to changes in the ozone layer. One reason is that depletion of the ozone layer is most severe over Antarctica, which is not a heavily populated continent. It is also likely that the increase in the number of reported cases of melanoma since the 1990s is due in part to better diagnostic instruments and earlier diagnosis. A third reason is that recent advances in genetics indicate that heredity plays a larger role in melanoma than was thought to be the case in the 1980s. Still another reason is growing recognition that tanning beds, first introduced in the 1970s and increasingly popular until the early 2000s, are a major factor in increased rates of melanoma, particularly among young women. In 2015, Australia banned commercial tanning salons across the country, while the United States leaves regulation of commercial tanning to the individual states. As of 2021, 42 states and the District of Columbia either ban the use of tanning salons by teenagers below age 18 or require teens to obtain parental permission.

GENETIC FACTORS. The development of melanoma is thought to have a strong genetic link, since about 20% of people who develop melanoma also have family members with the disease. Researchers have identified mutations in genes on chromosomes 1, 9, and 12 as linked to familial melanoma, including a gene called *BRAF* that plays a role in the development of melanoma. A mutated form of *BRAF* is thought to switch on the malignant cells, allowing them to grow and divide. A positive family history of one or two first-degree relatives having had melanoma substantially increases the patient's risk for developing the disease. There is also a syndrome known as dysplastic (atypical) nevus syndrome that is characterized by atypical moles in children under age 10. Such individuals have to be monitored closely for the development of malignant melanoma.

There are mutations in about half of familial melanoma patients of the tumor-suppressing gene *CDKN2A* (also known as the *p16* gene) on chromosome 9. Mutations in another tumor suppressor gene known as *CDK4* have also been linked to melanoma. Still other genes linked to an increased risk of melanoma include *RBI*, *NF1*, *PTEN/MMAC1*, and *NRAS*. Mutations in the *NRAS* gene on chromosome 1 are found in 15% to 20% of melanomas; these melanomas are more aggressive and have a poorer prognosis than tumors without the mutation.

In addition to the genetic mutations in melanoma cells associated with early UV damage to the skin, there is evidence that more radical alterations occur at a rapid pace in end-stage disease, resulting in chaotic changes to

the genome that include increased ploidy (the number of complete chromosomes in a cell), doubling of the entire genome, and mutations in genes that ordinarily protect the integrity of the genome.

Symptoms

The first sign of melanoma is a mole, discolored lump, or other growth found on the skin. Melanomas can occur anywhere on the body, but they are most often found on the backs of men and the legs of women. Generally, melanomas are black or brown, but they may be red, skin-colored, or white. Some may develop pinkish or bluish patches mixed in with darker areas.

Changes in a mole's appearance over time may also indicate malignant melanoma. Sometimes, a growth or mole may bleed, ooze, or itch, which indicates malignancy. Having satellite moles, new moles that grow near an existing mole, may also point to this form of skin cancer. Early-stage melanomas may itch or shed small flakes of skin, while more advanced melanomas may bleed or ooze fluid as well as itch. Advanced melanomas may also become hard or lumpy in texture. However, melanomas usually do not cause pain.

People with moles, lumps, or growths that fit these criteria should be checked by a doctor.

Diagnosis

Diagnosis of melanoma begins with careful examination of the skin.

Examination

Anyone who finds an abnormal mark or mole on the skin should contact their health care provider for a skin examination. About 80% of all skin cancers are first noticed by the patient. The doctor or nurse will carefully examine all moles, birthmarks, and pigmented areas over the person's entire body, including the back, legs, hands, feet, and scalp.

Doctors often use the ABCDE mnemonic when making a diagnosis of melanoma. The letters stand for the following signs:

- **Asymmetry:** Melanomas are usually asymmetrical, with one half different from the other. A normal mole is round, whereas a suspicious mole is unevenly shaped.
- **Border:** The edges of a melanoma may be ragged or blurred. A normal mole has a clear-cut border with the surrounding skin, whereas the edges of a suspect mole are often irregular or scalloped.
- **Color:** A malignant melanoma often has several colors or shades, whereas benign moles are typically one color. Normal moles are uniformly tan or brown, but cancerous

moles may appear as mixtures of red, white, blue, brown, purple, or black.

- **Diameter:** Cancerous moles are usually larger than a pencil eraser or pea (about 6 millimeters or 1/4 inch).
- **Evolution:** A mole that changes over time in color or shape or develops itchiness or bleeding should be reported to the doctor.

A family doctor can often spot suspicious-looking changes in a patient's skin, but they will usually refer the patient to a dermatologist for a definite diagnosis. Dermatologists are doctors with specialized training in diagnosing and treating skin disorders.

To diagnose cutaneous melanoma, a dermatologist will first use a dermatoscope, which is a special palm-sized instrument with a magnifying lens and built-in light. Most modern dermatoscopes allow the doctor to toggle between polarized and nonpolarized light in order to study a mole or other skin feature in detail. The use of dermatoscopes has increased the accuracy of diagnosing malignant melanoma considerably, because the doctor can make digital images of suspicious moles or skin areas and save them for comparison with images from later checkups.

Tests

As of 2021, there are no blood or other body fluid tests that can be used to diagnose melanoma. The diagnosis is usually made by a combination of tissue analysis and (for advanced-stage disease) imaging studies. Most patients who consult a doctor have an early-stage melanoma, and extensive testing is not usually warranted. It is important to see a doctor promptly when melanoma is suspected, however; the pausing of routine office visits during COVID-19 lockdowns has already resulted in a growing number of patients whose melanomas increased in severity, with consequent worsening of outcomes.

In regard to genetic testing, most people who develop melanoma do *not* have a genetic mutation associated with this type of cancer. The American Academy of Dermatology does, however, recommend genetic counseling and possibly genetic testing for patients with one or more of the following characteristics:

- Three or more melanomas that grew deep into the skin or spread, especially if the first melanoma was diagnosed before age 45.
- Three or more blood relatives on one side of the patient's family who have had melanoma or cancer of the pancreas.
- Two or more Spitz nevi, which are benign red or reddish-brown colored patches of skin that can be difficult to distinguish from melanomas; they are usually removed by dermatologists even though they are benign.

- One or more Spitz nevus in addition to a close relative diagnosed with uveal melanoma, mesothelioma, or meningioma.

If the patient has signs or symptoms of more advanced disease, or if the lesion has penetrated deeply into the skin, imaging studies may be appropriate. These would involve CT scans of the abdomen, the chest, or regional nodal areas, or a CT or MRI of the brain. A positron emission tomography (PET) scan may also be used to look for melanoma metastases. PET scans involve the use of radioactive glucose to look for cancer cells, as cancers take up sugar more rapidly than normal tissues do.

Procedures

BIOPSY. If the dermatoscope images suggest that the patient may have melanoma, the next step is to take a sample of the abnormal mole or area of skin to be sent to a laboratory for analysis under a microscope. This procedure is called a biopsy. In the case of melanoma, the doctor will remove the entire mole rather than just a portion of it, in order to obtain an accurate measurement of its depth. It is important to establish the exact thickness of penetration of the primary tumor. If a skin lesion is suspicious, full-thickness excisional biopsy is the approach recommended. Shave biopsies and biopsies that remove only a portion of the suspect area are inappropriate. Often, in an early case, the excision involves just the suspicious lesion with minimal normal skin, but it should be a full vertical excision of the skin. Biopsies are done under topical or local anesthesia.

To evaluate whether the melanoma may have spread beyond the skin, the doctor may perform a sentinel lymph node biopsy. A sentinel lymph node is the lymph node closest to the melanoma, the one to which it is most likely to spread.

STAGING. Malignant melanoma is curable if caught early. When a melanoma is not removed in its early stages, however, cancer cells will start to grow downward from the skin surface and invade healthy tissue. The disease can then spread to other parts of the body. Measuring a cancer's size, thickness, and likelihood of spreading is called staging. Melanomas are graded in five stages, from 0 to 4. The chief factor in determining a patient's chances of recovery is the thickness of the melanoma, known as the Breslow depth or Breslow measurement.

The five stages of melanoma are defined by the American Joint Committee on Cancer (AJCC) Tumor-Node-Metastasis (or TNM) system:

- **Stage 0:** The cancerous cells are found only in the outer layer of skin (Tis) and have not spread to nearby lymph nodes (N0) or other parts of the body (M0). At this stage,

the cancer is called melanoma in situ. The five-year survival rate is 99.9%.

- **Stage I:** The melanoma is no more than 2/25 of an inch thick (2 mm) and may or may not be ulcerated (T1 or T2a). It has not spread to nearby lymph nodes (T0) or other parts of the body (M0). Five-year survival rate is 98%.
- **Stage II:** The tumor is more than 1 mm thick (T2b or T3) or may be 4 mm thick (T4) but has not spread to nearby lymph nodes (N0) or distant organs (M0). Survival rate is 81%.
- **Stage III:** The melanoma has spread to nearby lymph nodes or to skin just outside the original tumor (satellite tumors). Stage III is subdivided into four substages (IIIA, IIIB, IIIC, and IIID) according to the tumor's thickness, the number of lymph nodes affected, and whether or not the tumor is ulcerated. In none of these substages has the tumor spread to other parts of the body (M0). Survival rate after five years is 65%.
- **Stage IV:** The primary tumor may be any size (any T). Melanoma cells have spread to other organs (M1), most often the lungs, liver, brain, and bones; to lymph nodes (any N); or to skin areas far away from the original tumor. The 5-year survival rate is 25%.

Treatment

Traditional

SURGERY. The only definite cure for malignant melanoma is surgical removal of the cancerous mole or patch of skin before the melanoma reaches a depth of 1 millimeter. The surgeon will remove a margin of normal skin surrounding the melanoma, as well as the tumor itself, to make sure that no cancerous cells are left behind.

A procedure known as microscopically controlled excision—also known as Mohs surgery after the physician who developed it in 1938—can be used to examine each layer of skin as it is removed to ensure that the proper amount is taken. Depending on the amount of skin removed, the cut is either closed with stitches or covered with a skin graft. When surgical excision is performed on such visible areas as the face, cosmetic surgery may also be performed to minimize the scar. Other techniques for removing skin tumors include burning; freezing with a probe containing liquid nitrogen (cryosurgery); or laser surgery. For skin cancer that is localized and has not spread to other areas of the body, excision may be the only treatment needed.

For advanced melanoma that has moved beyond the original tumor site, the local lymph nodes may be surgically removed. In some cases in which the melanoma

has penetrated deeply into a finger or toe, amputation of the digit may be necessary, but these cases are rare.

IMMUNOTHERAPY. Immunotherapy in the form of interferon or interleukin was used in the past as adjuvant therapy for advanced melanoma to stimulate the immune system. However, these agents had severe side effects that some patients could not tolerate. As of 2021, interferon is used only infrequently, because newer agents have proven much more effective.

One newer drug used in immunotherapy for advanced-stage melanoma is ipilimumab (Yervoy), a synthetic version of an immune system antibody. Ipilimumab works by blocking CTLA-4, a protein on the surface of T cells that acts as a brake on T cell activation. In 2014, the Food and Drug Administration (FDA) approved two new drugs that act in similar ways: pembrolizumab (Keytruda) and nivolumab (Opdivo); and in 2016, the FDA approved the use of ipilimumab and nivolumab as combination immunotherapy for patients with inoperable stage IV melanoma.

In 2015, the FDA approved a new type of immunotherapy called oncolytic virus therapy, which uses a herpesvirus altered in a laboratory, to infect and kill cancer cells. The only drug in this class as of 2021 is talimogene laherparepvec, or T-VEC (Imlygic), which is injected directly into the tumors of metastatic melanoma. It stimulates the patient's immune system to attack cancer cells and kill them directly.

TARGETED THERAPY. Targeted therapy is a newer type of treatment for advanced melanoma. It is a type of drug therapy that blocks the growth of skin cancers by interfering with signaling pathways or specific molecules that the cancer cells need for growth. There are several types of targeted therapy drugs used for melanoma as of 2021. One group targets melanoma cells with mutations in the *BRAF* gene; it includes drugs like vemurafenib (Zelboraf), encorafenib (Braftovi), and dabrafenib (Tafinlar), which attack the BRAF protein directly and shrink metastatic tumors, thus prolonging the patient's survival time.

Newer targeted therapy drugs include the MEK inhibitors, which inhibit the action of two enzymes known as MEK1 and MEK2, which work together with the BRAF protein to regulate cell growth. MEK inhibitors approved by the FDA include trametinib (Mekinist), cobimetinib (Cotellic), and binimetinib (Mektovi). The next step in development of targeted therapy is to combine BRAF inhibitors and MEK inhibitors. As of 2021, the FDA has approved three such combinations: dabrafenib-trametinib (Tafinlar-Mekinist); encorafenib-binimetinib (Braftovi-Mektovi); and vemurafenib-cobimetinib (Zelboraf-Cotellic).

Some acral melanomas contain mutations in the *c-KIT* proto-oncogene; they may respond to treatment

with imatinib (Gleevec) or nilotinib (Tasigna), drugs that are known to affect cells with *c-KIT* mutations.

TOPICAL MEDICATIONS. Some early-stage melanomas may be treated with imiquimod (Zyclara), a topical medication applied as a cream. It is used most often in areas where surgery would be disfiguring. More recently, researchers in Italy reported success in treating a patient with later-stage melanoma with imiquimod, and a group of dermatologists in Michigan reported similar success in combining imiquimod with shave excision and electrodesiccation in treating metastatic melanoma.

RADIOTHERAPY. Though radiation therapy has a minimal role in the primary treatment of malignant melanoma, for patients who have metastatic disease it may be helpful in symptom relief in patients who have developed tumor deposits in such areas as the brain or bone. Therapy that is intended to relieve the symptoms of the disease, rather than cure it, is called palliative therapy.

CHEMOTHERAPY. Chemotherapy can be used to treat metastatic melanoma; however, it is not usually used as first-line therapy, because melanomas are much more resistant to chemotherapy than other cancers. The chemotherapeutic agent dacarbazine, or DTIC, seems to be the most effective agent. Combination chemotherapy may be an option. Other chemotherapy drugs that may be used include vinblastine, carboplatin, and temozolomide. Chemotherapy is more often administered in combination with targeted therapy than used by itself.

VACCINES. Vaccines for metastatic melanoma are being studied in clinical trials but were still considered experimental as of 2021. Promising candidate vaccines are made from dendritic cells (DCs), specialized cells in the immune system that stimulate T cells to attack cancerous tumors. There are 88 clinical trials of dendritic cell vaccines against melanoma registered with the National Institutes of Health as of mid-2021. Most of these trials combine administration of the vaccines with cancer chemotherapy to patients with advanced melanoma.

Alternative and complementary therapies

There are no established alternative treatments for skin cancer. Preventive measures that can be helpful include regular skin self-examination; minimizing exposure to the sun and sunburn; and eating a diet high in antioxidants.

Patients diagnosed with melanoma may benefit from some complementary therapies such as prayer, meditation, humor therapy, art therapy, pet therapy, and aromatherapy. While these approaches should not be used as replacements for conventional treatments, they can help to lift the patient's spirits.

QUESTIONS TO ASK YOUR DOCTOR

- Have you ever had a patient who asked you to look at a suspicious mole or skin lesion?
- If so, did you refer the patient to a dermatologist?
- Why do you think the rate of melanoma keeps rising in North America and countries like Australia?
- The FDA first proposed federal legislation banning minors from using tanning salons anywhere in the United States in 2015. Do you think such legislation is a good idea, or should regulation of tanning salons continue to be left to the states?

Look Good Feel Better is a free public service program approved by the American Cancer Society; it helps patients with any kind of cancer cope with changes in their looks related to cancer treatment. It began in 1987 when a doctor asked the president of the Personal Care Products Council to help a patient who was so depressed by her appearance during chemotherapy that she refused to leave her hospital room. The president sent a makeup artist to visit the patient, who was so delighted with her makeover that she began to respond better to her cancer treatment. Look Good Feel Better has expanded to include programs for teens, men, and Spanish-speaking patients; groups are available in all 50 states, the District of Columbia, and Puerto Rico. The main website is <http://www.lookgoodfeelbetter.org>.

Prognosis

The prognosis of melanoma is influenced by a number of factors, according to the AJCC:

- Thickness of the primary melanoma (Breslow's depth); the thicker the tumor, the worse the prognosis.
- Presence of ulceration or bleeding of the primary melanoma. Ulceration or bleeding increases the risk of metastasis.
- Number of lymph nodes involved.
- Location of the primary melanoma: location on the extremities has a better prognosis than a location on the head, neck, or chest.
- Metastasis to distant sites, with metastases to the lungs or skin having a better prognosis than metastases to the brain, liver, or bones.
- Patient's sex: Women have better prognoses in most cases than men.

- Patient's age: Younger patients have better prognoses than older adults.
- Presence of genes that are considered unfavorable; these include *MCM6* and *TIMELESS* as well as *BRAF*, *CDKN2A*, and *NRAS*.

Melnick-Fraser syndrome see **Branchiootorenal syndrome**

Menkes syndrome

Definition

Menkes syndrome is a sex-linked recessive condition characterized by seizures and neurological deterioration, abnormalities of connective tissue, and coarse, kinky hair. Affected males are often diagnosed within the first few months of life and die in early childhood.

Description

Menkes syndrome is also known as Menkes disease and kinky hair syndrome. It was originally described in 1962, based on the report of a family of English and Irish descent who had five male infants with a distinctive syndrome of progressive neurological degeneration, peculiar hair, and failure to thrive. Each of the boys appeared normal at birth but after several months, developed seizures and began to regress in their physical skills. Each child died at an early age, with the oldest surviving to be three-and-one-half years old. In 1972, Menkes syndrome was linked to an inborn copper deficiency. It is now clear that this lack of copper, an essential element for normal growth and development, inhibits the work of specific enzymes in the body. The clinical signs and symptoms of Menkes syndrome are a direct result of these biochemical abnormalities.

Approximately 90%–95% of patients with Menkes syndrome have a severe clinical course. This represents classical Menkes syndrome. Males with milder forms of Menkes syndrome have also been described. The mildest presentation is now known as occipital horn syndrome (OHS), which is allelic to Menkes syndrome; both conditions are due to different mutations in the same gene. Mutations responsible for OHS primarily cause connective tissue abnormalities and have significantly milder effects on intellectual development. Individuals with OHS live longer than those with classical Menkes syndrome.

Genetic profile

Menkes syndrome is an X-linked recessive condition. The gene, which was identified in 1992, is located on the long arm of the X chromosome at band 13.3

(Xq13.3). It is extremely unusual for a female (with two X chromosomes in her cells) to be affected, although it has been reported. Males, who have only one X chromosome, make up the overwhelming majority of patients.

Approximately one-third of affected males are due to a new mutation in the mother's egg cell. There is usually a negative family history, or no other affected male family members. When the mutation occurs as an isolated, random change, the mother's risk of having another affected son is low.

On the other hand, the remaining two-thirds of affected males are born to carrier mothers. Often, there is a family history of one or more affected male relatives (e.g., uncle, brother, cousin), all of whom are related to one another through the maternal side. Carrier females are normal but face a risk of passing on the gene for Menkes syndrome to their children. A carrier mother has a 25% risk of having an affected son, a 25% risk of having an unaffected carrier daughter, a 25% risk of having a normal son, and a 25% risk of having a normal, non-carrier daughter. These risks apply to each pregnancy.

The Menkes syndrome gene, also known as *MNK* or *ATP7A*, is a large gene known to encode a copper-transporting protein. Individuals with Menkes syndrome have low levels of copper in their blood. Their cells are able to take in copper but the metal is unable to leave the cell and be delivered to crucial enzymes that require copper in order to function normally. As a result, copper accumulates in the body tissues, and clinical abnormalities occur. Most symptoms of Menkes syndrome, such as skeletal changes and abnormal hair, may be explained by the loss of specific enzymes. However, the reasons for the brain degeneration are still not entirely clear.

A variety of mutations that cause Menkes syndrome have been identified in the *MNK* gene. Unfortunately, almost every family studied has had a unique mutation. This makes genetic testing difficult, particularly if the mutation in the family has not yet been determined. OHS is also caused by mutations in the *MNK* gene.

Demographics

Menkes syndrome is relatively rare, with an estimated incidence of 1 in 100,000–250,000 male births. Among the 3.5 million infants born annually in the United States, approximately 15–35 males have Menkes syndrome.

Signs and symptoms

Infants with classical Menkes syndrome appear normal at birth and continue to develop normally for roughly the first eight to ten weeks of life. At approximately two

to three months of age, affected infants begin to lose previously attained developmental milestones, such as head control and a social smile. They lose muscle tone and become hypotonic, or floppy, develop seizures, and begin to fail to thrive. Changes in the appearance of their face and hair become more apparent. A diagnosis of Menkes syndrome is often made around this time.

Menkes syndrome has several clinical features.

Neurologic features include:

- mental deterioration and handicap due to structural and functional brain abnormalities
- seizures
- inability to regulate body temperature (hypothermia)
- feeding and sleeping difficulties
- decreased muscle tone

Connective tissues typically display:

- tortuous blood vessels due to abnormal formation of blood vessel walls
- abnormalities of bone formation, as noted by x-ray (skull, long bones, and ribs)
- bladder diverticulae
- loose skin, particularly at the nape of neck, under the arms, and on the trunk
- loose joints

Other clinical features are:

- unusual facial features (jowly, pudgy cheeks, large ears)
- abnormal hair, including the eyelashes and eyebrows
- light skin and hair coloring (hypopigmentation)
- delayed eruption of teeth
- impaired vision
- normal hearing

The hair of individuals with Menkes syndrome deserves special discussion, particularly since this condition is sometimes called kinky hair syndrome. Abnormal hair is not typically evident during the first few months of life. However, around the time that the other physical signs of the disorder become more apparent, the hair takes on an unusual appearance and texture. On magnified inspection, it is short, sparse, coarse, and twisted. It has been likened to the texture of a steel wool cleaning pad. It shows an unusual orientation, referred to as *pili torti*, a 180 degree twist of the hair shaft. It is usually fragile and breaks easily. The hair of all affected individuals shows these characteristic changes; it is likewise present in some women who are known gene carriers.

Death occurs early in males with Menkes syndrome, often by the age of three years in classical disease. Longer survival is not unusual and is most likely due to recent

improvements in medical care. Severity of disease and its rate of progression are fairly consistent among untreated males in a single family.

Diagnosis

An initial diagnosis of Menkes syndrome is usually suspected based on the combination of physical features. As these features are generally subtle in the newborn period, they may be missed—particularly if there is no prior family history of the condition.

A common prenatal and newborn history has been recognized among affected infants. The histories often include: premature labor and delivery; large bruises on the infant's head after an apparently normal, uncomplicated vaginal birth; hypothermia; low blood sugar (hypoglycemia); and jaundice. Hernias may be present at either the umbilicus or in the groin area. These findings are non-specific and occur in normal pregnancies and unaffected infants. However, their presence may alert a knowledgeable physician to the possibility of Menkes syndrome, especially when other clinical signs are also present.

A clinical diagnosis is strongly supported by decreased serum levels of copper and ceruloplasmin, a protein in the blood to which the majority of copper is attached. Abnormal results, however, do not confirm the diagnosis since both copper and ceruloplasmin levels may also be low in normal infants during the first few months of life. A definitive diagnosis of Menkes syndrome is possible by either specific biochemical analysis to measure the level of copper accumulation in the cells, or by identification of the responsible mutation in the *MNK* gene. Both types of analysis represent highly specialized testing and are available only through a limited number of laboratories in the world.

Prenatal diagnosis, in the context of a family history of the disorder, is possible. Ideally, a woman's carrier status will have been determined prior to a pregnancy as carrier detection may be difficult and time-consuming. Mutation analysis is the most direct and accurate way to determine carrier status. In order for this to be possible, the *MNK* mutation in an affected family member must have been previously determined. Linkage analysis is another possibility but requires blood samples from other family members, including the affected relative, to facilitate interpretation of results. If the affected relative is deceased, a stored DNA sample may be used.

Other, non-molecular methods of carrier detection include analysis of hair samples to look for areas of *pili torti*, increased fragility, or hypopigmentation. Skin cells cultured in the laboratory may be used to measure the accumulation of radioactive copper. However, these

KEY TERMS

Catecholamines—Biologically active compounds involved in the regulation of the nervous and cardiovascular systems, rate of metabolism, body temperature, and smooth muscle.

Connective tissue—A group of tissues responsible for support throughout the body; includes cartilage, bone, fat, tissue underlying skin, and tissues that support organs, blood vessels, and nerves throughout the body.

Diverticulae—Sacs or pouches in the walls of a canal or organ. They do not normally occur, but may be acquired or present from birth. Plural form of diverticula.

Enzyme—A protein that catalyzes a biochemical reaction or change without changing its own structure or function.

Jaundice—Yellowing of the skin or eyes due to excess of bilirubin in the blood.

Linkage analysis—A method of finding mutations based on their proximity to previously identified genetic landmarks.

Tortuous—Having many twists or turns.

approaches are not always reliable, even in known carriers.

If a woman is found to be a non-carrier, prenatal testing for Menkes syndrome is generally not necessary in any of her pregnancies. However, in the event that a woman is a confirmed carrier, prenatal testing such as chorionic villus sampling (CVS) or amniocentesis may be offered. Ultrasound examinations alone will not assist in making a diagnosis. CVS or amniocentesis will determine the fetal sex: if female, additional testing is usually not recommended since carrier daughters would be expected to be normal. Carrier testing on the daughter may be performed after birth, if desired, or postponed until later in life.

Further testing is offered when a fetus is male. If mutation studies cannot be performed because the mutation in the family is unknown, biochemical analysis may be attempted. Biochemical testing has serious drawbacks, and a correct diagnosis may not always be possible. Tissue obtained during CVS normally has a very low copper content and is very susceptible to contamination by maternal tissue or by outside sources, such as laboratory instruments or containers. As a result, if the copper level exceeds a certain level, an unaffected pregnancy could

potentially be falsely identified as affected. Specific handling precautions are necessary to minimize this risk.

Similar concerns exist for a sample obtained by amniocentesis. Ordinarily, the cells obtained from this procedure are cultured and grown in the laboratory. A measurement is taken of the total amount of accumulated copper over a certain period. The timing of amniocentesis in the pregnancy is critical because the amniotic fluid cells do not grow as rapidly after a gestational age of 18 weeks. Problems in cell growth cause significant difficulties in the interpretation of the biochemical results.

Other methods of diagnosis are being investigated. Promising methods include an assessment of the concentration of copper in a sample of the placenta (extremely high in affected pregnancies), and the level of catecholamines (low) in a sample of blood from the umbilical cord. Both methods, which are fast, reliable, and performed immediately after delivery, clearly require a high level of suspicion of the disorder. In most cases, this will be based on a history of a previous affected son, abnormal or unclear prenatal testing results, or both. Women who do not have a family history of Menkes syndrome, and are therefore not expected to be at-risk, are not offered this testing.

Treatment and management

The underlying, critical problem for patients with Menkes syndrome is an induced copper deficiency. Copper uptake is normal but the gene abnormality prevents the release of copper to the appropriate enzymes in the cells. Copper accumulates in the intestinal system, and patients are unable to meet their most basic nutritional needs. The most serious effects are apparent during the first year of life when growth of the brain and physical development are occurring most rapidly. Copper is required in order for both of these processes to occur normally.

Treatment of Menkes syndrome has focused on providing patients with an extra source of copper to try to deliver it to the enzymes that need it for normal function. Studies at the National Institutes of Health (NIH) have focused on the use of a copper-histidine compound in affected males. Copper-histidine is normally present in human serum and is most likely the form in which copper is absorbed by the liver. Also, in the laboratory, the presence of histidine in serum has been shown to increase the uptake of copper. Daily injections are the most successful form of treatment to date.

Two conclusions have been drawn from this work: (1) Treatment is more successful when started at an early age. Most, but not all, treated boys have achieved more normal developmental milestones and have had milder mental impairment. (2) Treatment is much less effective

QUESTIONS TO ASK YOUR DOCTOR

- What is the expected lifespan for a child born with Menkes syndrome?
- If my sister had a child with this disorder, is there any way of knowing what the probability is of my having a child with the same disorder?
- What are the most common signs and symptoms associated with Menkes syndrome?
- Can you recommend brochures, pamphlets, or other sources of information about this disorder?

if started after the age of several months, or when neurologic symptoms have already begun. While milder improvements in the areas of physical development, personality, and sleeping habits have been reported in boys whose treatment started later, the degree of mental handicap has not been significantly altered.

A separate study in 1998 lent further support to these results. This study followed four affected males with classical Menkes syndrome, all of whom were started on copper-histidine treatment soon after birth. Three of the four males were born into families with other affected relatives; the fourth child was diagnosed at the age of three weeks. All four showed significant improvements in their development and clinical course. None of them experienced entirely normal development, but their remaining clinical abnormalities were similar to those seen in patients with occipital horn syndrome. The oldest survivor of the group was 20 years old.

This information strongly supports the importance of nutritional therapy in the care of patients with Menkes syndrome. Early treatment is best but requires early diagnosis. It should also not be seen as a “cure.” It has been shown to lessen the severity of the syndrome but not eliminate it. Thus, prenatal diagnosis, and its possible limitations, should continue to be discussed with prospective parents known to be at risk. Mutation studies should be performed, whenever possible, to increase the accuracy of testing results.

Prognosis

Death often occurs by the age of three years in untreated males with classical Menkes syndrome, although longer-term survivors have been reported. Treatment with supplemental copper has resulted in improved physical development, milder mental handicap, and extended lifespan in some affected males. However, not all patients have responded to the same extent.

Additionally, patients treated after the onset of symptoms have done worse than those treated before symptoms occur. Research is continuing to refine the best dosage of copper-histidine, determine the optimal timing and route of treatment, and develop newer treatment strategies.

Metaphyseal dysplasia

Definition

Metaphyseal dysplasia, also known as metaphyseal chondrodysplasia, is a very rare disorder in which the outer part of the shafts of long bones is unusually thin with a tendency to fracture. Aside from valgus knee deformities (commonly known as knock-knee), many patients with metaphyseal dysplasia exhibit few or no symptoms. The disorder comes in a variety of forms, some of which cause serious problems including intellectual disability, blindness, and deafness.

Description

Metaphyseal dysplasia is frequently mistaken for craniometaphyseal dysplasia, a disorder characterized by

the thickening of the bones of the head. Metaphyseal dysplasia is genetically distinct from craniometaphyseal dysplasia and has only mild effects on the skull. In fact, metaphyseal dysplasia is so subtle that often it cannot be detected by clinical observation and is uncovered only when x-rays are taken for another purpose. The signs are immediately visible on x-rays, particularly the cone-like flaring that occurs on the tubular bones of the leg. This flaring is similar in shape to the Erlenmeyer glass flasks used in laboratories.

Another name for metaphyseal dysplasia is Pyle's disease, after Edwin Pyle, an orthopedic surgeon who first described it in 1931.

There are eight varieties of metaphyseal dysplasia. They are classified as Jansen type, Schmid type, McKusick type, metaphyseal anadysplasia, Shwachman-Diamond metaphyseal dysplasia, adenosine deaminase deficiency, Spahr-type metaphyseal chondrodysplasia, and metaphyseal acroscaphodysplasia.

Genetic profile

Inheritance of metaphyseal dysplasia is typically autosomal recessive, meaning that both parents are carriers of an abnormal gene when a child exhibits symptoms. Children inheriting the gene from one parent become carriers. When both parents are carriers, each child has a 25% chance of having the disorder and a 50% chance of being a carrier. In the case of Jansen type metaphyseal dysplasia, the chromosomal gene locus is 3p22-p21.1. In Schmid type metaphyseal dysplasia, the locus is 6q21-q22.3. For McKusick type (cartilage-hair hypoplasia), it is 9p13. In adenosine deaminase deficiency, the locus is 20q-13.11. The modes of inheritance for Jansen type, Schmid type, and adenosine deaminase deficiency are all autosomal dominant, meaning that a child may inherit the disorder if just one parent is a carrier. For all other varieties of metaphyseal dysplasia, the modes are autosomal recessive, with the possible exception of metaphyseal anadysplasia, which may be X-linked recessive. In that case, whenever one parent is a carrier of the disorder, each child would have a chance of either inheriting it or being a carrier.

The Schmid type of metaphyseal dysplasia has been connected to a mutation in the *COL10A1* gene, which codes for type X collagen $\alpha 1$ chain, which—although not fully understood—does play a role in the ossification of collagen. This mutation has been linked to a substitution mutation.

Demographics

This disorder is very rare, and the number of recorded cases is too small to draw firm demographic conclusions. There appears to be no preference based on sex.

KEY TERMS

Carrier—An individual who possesses an unexpressed abnormal gene of a recessive genetic disorder.

Dysplasia—The abnormal growth or development of a tissue or organ.

Metaphysis—An area of softer bone and cartilage in long bones between the diaphysis (shaft) and epiphysis (end).

Splay—Turned outward or spread apart.

Signs and symptoms

The characteristic sign of metaphyseal dysplasia is splaying of the long bones, more severely than in craniometaphyseal dysplasia. Gross Erlenmeyer flask flaring is seen in the tubular bones of the leg, particularly in the femur. Unlike craniometaphyseal dysplasia, few signs occur in the skull in metaphyseal dysplasia, apart from protrusions over the eye sockets.

Metaphyseal dysplasia is also marked by expanded bones of the rib cage and pelvis and by changes in the angle of the lower jaw. The humerus bone of the arm tends to be unusually broad. Other signs include scoliosis (a sideways curvature of the spine) and osteoporosis (a condition that makes bones brittle). Patients may complain of muscle weakness or joint pain. Dentists may notice malocclusion, an inability of the teeth to properly close. Some spinal changes are possible, associated with the flaring of tubular bones. These may include platyspondyly, a broadening of the vertebrae.

Jansen type

In addition to the mentioned signs, Jansen type metaphyseal chondrodysplasia is characterized by short arms, legs, and stature (short-limbed dwarfism), which become apparent during early childhood. Affected children experience a gradual stiffening and swelling of their joints. Often, they develop a characteristic “waddling gait” and a stance that appears as if they were squatting. Some facial abnormalities may be evident at birth. These include prominent, widely spaced eyes, a receding chin, or a highly arched palate. Some affected adults develop unusually hardened bones in the back of the head, which sometimes results in deafness and/or blindness. Abnormal cartilage development may harden into rounded bone masses that may be noticeable on the hands, feet, and elsewhere. Other signs and symptoms associated with Jansen type metaphyseal chondrodysplasia include clubbed fingers, a fifth finger permanently fixed in a bent position, fractured ribs,

intellectual disability, psychomotor retardation, and high blood levels of calcium. Curvature of the spine in these patients may be front-to-back as well as sideways. Testing the blood and urine for calcium can assist in confirming a diagnosis. Jansen type metaphyseal chondrodysplasia was formerly referred to as metaphyseal dysostosis. This type of metaphyseal dysplasia is possibly due to a deleterious mutation in the gene *Zfp521*, which codes for a parathyroid related protein receptor that has a large role in the proliferation and differentiation of cells at the growth plate, leading to these skeletal abnormalities.

Schmid type

Like Jansen type metaphyseal chondrodysplasia, Schmid type metaphyseal chondrodysplasia is also characterized by short-limbed dwarfism. Other special features may include an outward flaring of the lower rib cage, bowed legs, leg pain, a normal spine, and a hip deformity that causes the thigh bone to angle toward the body's center. Schmid type metaphyseal chondrodysplasia was first discovered in 1943 in a family of Mormons that had experienced 40 cases of the disorder over four generations. The first affected ancestor was traced back to 1833. This type of metaphyseal dysplasia is caused by a mutation of the *COL10A1* gene located on chromosome 6 due to a deletion that causes a frameshift.

McKusick type

Like Jansen type and Schmid type, McKusick type metaphyseal chondrodysplasia is marked by short-limb dwarfism. Other features include thin, light-colored hair, loose-jointed fingers, elbows that cannot be fully extended, Hirschsprung disease (a birth defect in which the usual nerve network fails to develop around the rectum, and in some cases, the colon), and abnormalities of the immune system. In the shin, the tibia bone is uncharacteristically shorter than the fibula. Patients are at increased risk of developing cancers, especially of the skin and the lymph nodes. McKusick type metaphyseal chondrodysplasia is also known as cartilage hair hypoplasia syndrome. The disorder was first recognized in 1965 among the Old Order Amish.

Metaphyseal anadysplasia

First noticed in 1971, metaphyseal anadysplasia is a form of metaphyseal dysplasia that starts early. Instead of appearing after puberty, some signs are found to be present at birth, but disappear after several years. In the thigh bones of patients studied, there was an unusually low level of red blood cell production.

Shwachman-Diamond syndrome

In addition to the skeletal system, Shwachman-Diamond syndrome also affects the pancreas. It is

QUESTIONS TO ASK YOUR DOCTOR

- Can you explain the meaning of the term "metaphyseal dysplasia"?
- How is this disorder transmitted from one generation to the next?
- How do the various types of metaphyseal dysplasia differ from each other?
- Are people with metaphyseal dysplasia able to live a normal life and if not, what are the most serious problems they will face?

characterized by inadequate absorption of fats because of abnormal pancreatic development and bone marrow dysfunction. Other unusual symptoms and signs include short stature, liver abnormalities, and low levels of any or all blood cells. Reduced levels of white blood cells may cause these patients to be vulnerable to repeated bouts with pneumonia, otitis media, and other bacterial infections. Shwachman-Diamond syndrome is also referred to as Shwachman-Bodian syndrome, Shwachman-Diamond-Oski syndrome, Shwachman syndrome, and congenital lipomatosis of the pancreas. Some researchers call it pancreatic insufficiency and bone marrow dysfunction.

Adenosine deaminase deficiency

A deficiency of adenosine deaminase (ADA), an essential, broadly distributed enzyme, causes severe combined immunodeficiency disease. This can bring about a wide range of effects, including asthma; pneumonia; sinusitis; diarrhea; problems with the liver, kidneys, spleen, and skeletal system; and failure to thrive. ADA deficiency is similar to McKusick type metaphyseal chondrodysplasia in that both disorders include skeletal changes and problems with cellular immunity. ADA deficiency earned a special place in genetics history in 1990, when, in the first application of gene therapy in humans, it was corrected using genetically engineered blood.

Spahr type metaphyseal chondrodysplasia

This is one of several disorders that used to be called metaphyseal dysostosis. It is extremely rare, and its features include severely bowed legs and short-statured dwarfism. In some cases, the bowing of the knees is so severe as to require surgical correction. Spahr type is very similar to Schmid type metaphyseal chondrodysplasia, except that inheritance is believed to be autosomal

recessive in Spahr type, unlike Schmid type, which is autosomal dominant.

Metaphyseal acroscyphodysplasia

This variety is also referred to as wedge-shaped or cone-shaped epiphyses of the knees. Its features include severely retarded growth, psychomotor retardation, abnormally small arms and legs, extremely short fingers, and curvature of the knees.

Metaphyseal dysplasia with maxillary hypoplasia and brachydactyly (MDMHB)

This type of metaphyseal dysplasia is an autosomal dominant pattern of inheritance classified by maxillary hypoplasia (softened facial bone), brachydactyly (shortness of the fingers and toes), metaphyseal flaring and thin diaphyseal cortices of long bones, increased size of the medial half of the clavicles, and malformed teeth, among other skeletal abnormalities. Studies have shown that this form of metaphyseal dysplasia is likely due to a duplication mutation of the *RUNX2* gene, which codes for the protein that regulates osteoblasts and chondrocytes.

Diagnosis

Diagnosis is usually by x-ray, in which the bone deformities of metaphyseal dysplasia are very noticeable, even if not apparent in a normal clinical examination. A medical doctor will look for valgus knee deformities. A radiologist will look for Erlenmeyer-flask-shaped femur bones and ensure that any deformities to cranial bones are minor in order to rule out craniometaphyseal dysplasia. The radiologist will also watch for abnormally broad humerus, radius, and ulna bones.

Treatment and management

Metaphyseal dysplasia cannot be directly treated, but some individual symptoms, such as osteoporosis or joint problems, may be treated or surgically corrected.

Prognosis

In many cases, patients with metaphyseal dysplasia may be symptomless and very healthy. Other patients, including those with Jansen type metaphyseal chondrodysplasia, may have more severe complications including blindness, deafness, or intellectual disability.

Methemoglobinemia, beta-globin type

Definition

Methemoglobinemia, beta-globulin type, formerly known as congenital methemoglobinemia, is an autosomal dominant inherited blood disorder. Its most distinctive characteristic is a cyanotic appearance, a bluish tint to the skin and mucous membranes. The condition is also known as hemoglobin M disease or blue baby syndrome.

Description

Methemoglobinemia is a malformation of the molecules associated with transporting oxygen to tissues and organs for the proper function of these tissues and organs. There are many types of methemoglobinemia, both hereditary and acquired. Acquired methemoglobinemia is often associated with drug use. Congenital methemoglobinemia, such as in the case of beta-globin type, is due to a mutation in the gene that codes for the correct synthesis of hemoglobin, an important molecule for the

binding of oxygen and then the releasing of it in its target tissue. More specifically, the iron portion of the heme molecule is not able to transform into its correct state, the ferrous state, for the proper binding and transfer of oxygen, so it remains in the ferric state. This causes a higher than normal (more than 1%) methemoglobin in the red blood cells. The defining and most prominent characteristic of methemoglobinemia is cyanosis, which may range from mild discoloration of the skin to an intense bluish color due to a lack of oxygen in the tissue. Symptoms of methemoglobinemia beta type appear as early as the age of three or four months.

Genetic profile

Methemoglobinemia beta type is due to a mutation in the *HBB* gene inherited as an autosomal dominant disorder. The hemoglobin molecule consists of four subunits, two of which are designated as alpha-globin and two of which are beta-globin. The hemoglobin, beta (*HBB*) gene carries instructions for the synthesis of the beta-globin unit of hemoglobin. Mutations in this gene result in the formation of an altered form of hemoglobin called M hemoglobin, which bonds abnormally with heme and reduces the molecule's ability to carry oxygen molecules. The *HBB* gene is located on the short arm of chromosome 11. Other disorders associated with mutations of this gene include sickle cell anemia and beta thalassemia, among others.

Signs and symptoms

The normal red color of blood is caused by hemoglobin-bonded oxygen (oxyhemoglobin). Hemoglobin with reduced amounts of oxygen retains the original color of the hemoglobin molecule itself, which is bluish brown. As a consequence, the common and predominant feature of methemoglobinemias such as methemoglobinemia beta-globin type is the bluish color imparted to the skin and mucous membranes, caused by blood vessels being close to the surface, a condition known as cyanosis. Symptoms are directly related to the amount of methemoglobin present in the blood and may range from simple cyanosis to neurological and/or cardiac symptoms due to hypoxia, and after that, death. A second cause of the disorder is mutations in the alpha-globin unit of the hemoglobin molecule that result in deficient production of the essential enzyme nicotinamide adenine dinucleotide (NADH) cytochrome b5 reductase. Four types of this form of congenital methemoglobinemia have been identified, depending on the locations of the body in which the defective enzyme occurs; therefore, differential diagnosis can occur via genetic testing.

KEY TERMS

Autosomal dominant—A pattern of inheritance in which only one copy of a defective gene on a nonsex chromosome is required for a disease or inherited trait to develop in an individual.

Congenital—Refers to a disorder that is present at birth.

Cyanosis—A bluish discoloration of the skin and mucous membranes.

Heme—An organic molecule that contains a single atom of iron and is responsible for the oxygen-carrying ability of hemoglobin.

Hemoglobin—A protein-iron compound in the blood that carries oxygen to the cells and carries carbon dioxide away from the cells.

Methemoglobinemia—A medical condition of the blood characterized by the presence of an altered form of hemoglobin, known as methemoglobin.

Plethora—An overabundance of something, in this case blood in the body.

Prevalence—The number of individuals living with a particular illness within a particular population at any given time. Prevalence is often expressed in terms of the number of individuals per 100 or per 1,000 members of the population.

Splenomegaly—Enlargement of the spleen.

Demographics

No estimates are available for the prevalence or incidence of methemoglobinemia beta-globin type either worldwide or in the United States. The disease is, however, classified as rare.

Diagnosis

The presence of cyanosis strongly suggests the possibility of methemoglobinemia beta-globin type. An initial follow-up test consists of a blood test for the presence of methemoglobin. The presence of this substance at concentrations greater than about 1% is considered evidence of methemoglobinemia. A simple confirmatory test is to bubble pure oxygen gas through the blood sample. Failure of the blood to turn red (evidence of its oxygenation) is considered confirmation of methemoglobinemia. Associated factors may be an overabundance of blood in the body (plethora) and enlargement of the spleen (splenomegaly). The differential diagnosis of methemoglobinemia beta-globin type

QUESTIONS TO ASK YOUR DOCTOR

- Are there signs or symptoms that indicate that more aggressive treatment for methemoglobinemia beta-globin type should be considered?
- What treatments are available for a patient in such circumstances?
- Although methemoglobinemia is generally a benign condition, are there circumstances in which more serious medical problems can arise?
- Under what circumstances are treatments with methylene blue and/or ascorbic acid indicated and recommended?

from other forms of methemoglobinemia and acquiring cyanosis can be done via genetic sequencing since there is now a known gene association.

Treatment and management

As of 2015, treatment of methemoglobinemia beta-globin type included methylene blue and ascorbic acid. Ascorbic acid (vitamin C) and methylene blue have been found to be partially successful in the treatment of certain cases. Although the condition is generally benign, the most serious cases are sometimes treated with exchange transfusions, in which large quantities of the patient's blood are removed and replaced with blood from a donor.

Prognosis

Methemoglobinemia beta-globin type is typically benign and does not normally require treatment. Patients should be observed for any change in condition and referred for medical treatment if any change is noted.

Methylenetetrahydrofolate reductase variant (MTHFR gene variant)

Definition

Methylenetetrahydrofolate reductase variants (MTHFR gene variants) are variants in the MTHFR gene that can result in reduced levels or malfunction of an enzyme called MTHFR. Most of these variants do not cause disease, but some result in high levels of the amino acid homocysteine. Some MTHFR variants may cause an increased risk of problems such as blood clots, high blood pressure, stroke, and heart disease. (Not all studies have found this association.) A few rare variants cause autosomal recessive homocystinuria, a genetic disorder that can feature developmental delays, seizures, eye disorders, blood clots, and bone fragility.

Description

The MTHFR gene contains the instructions for the production of methylenetetrahydrofolate reductase (MTHFR), an enzyme that the body uses to convert folate (vitamin B9) to a form that helps convert the amino acid homocysteine to methionine. The amino acid methionine is involved in a various processes in the body, including making proteins and other compounds. Methionine can also be obtained through diet. Some variants in the MTHFR gene can decrease the levels of MTHFR or cause it not to function properly, which results in higher amounts of homocysteine and lower amounts of methionine in the blood, a condition that can produce increased health risks in some people.

Genetic profile

The two most common MTHFR gene variants are C677T and A1298C. Like most genes, people normally

inherit two copies of the MTHFR gene, one from their mother and one from their father. Individuals with a C677T variant in both copies of their MTHFR genes can have slightly increased levels of homocysteine. The levels of homocysteine can be normal if they get enough folate from their diet. Individuals with one A1298C and one C677T variant tend to have slightly increased homocysteine, which can resolve with folate supplementation. Individuals with one C677T variant can have homocysteine levels that are slightly higher than normal but not as high as those with two C677T variants. Individuals with one or two A1298C variants tend to have normal levels of homocysteine.

At least 40 rare variants in the MTHFR gene can cause autosomal recessive homocystinuria. People with autosomal recessive homocystinuria have inherited one of these rare variants from their mother and one from their father. Their parents are called carriers since they each have one normal copy of their MTHFR gene and one copy with the rare variant. Two carriers have a one-in-four (25%) chance of having a child with homocystinuria, one-in-two chance (50%) of having a child who does not have the disease but is a carrier, and one-in-four (25%) chance of having a child with two normal copies of the gene. Carriers do not have homocystinuria but may be at increased risk for blood clots and strokes. C677T and A1298C are not associated with autosomal recessive homocystinuria.

Demographics

In the United States, the C677T variant is found in less than 1% of African Americans, but is more common among whites and found in 20% or more among Hispanics and Italians. The A1298C variant is less common than the C677T variant. About 17% of people in the United States have a combination of the C677T and A1298C variants. The variants that cause autosomal recessive homocystinuria are very rare.

Signs and symptoms

For most people, the common MTHFR variants C677T and A1298C are unlikely to cause problems even if they have increased levels of homocysteine. Some studies have found that higher levels of homocysteine and lower levels of methionine may cause an increased risk of blood clots, high blood pressure, stroke, and heart disease.

Women with two copies of the C677T variant appear to be at slightly increased risk of having a child with a neural tube defect (NTD). This severe defect causes the child to be born with an opening in the spine or skull, exposing the spinal cord or brain and possibly causing brain and nerve damage.

KEY TERMS

Amino acid—Organic compounds the body uses for many different processes. There are about 500 known amino acids but only 20 of them are related to DNA and combine together to form proteins.

Autosomal recessive—Condition caused by a pathogenic variant (mutation) in both copies of a particular gene. Two carriers of an autosomal recessive condition have a one-in-four (25%) chance of passing it on to their children.

Carrier—Person who has a pathogenic variant in one copy of a gene that causes an autosomal recessive condition. Carriers often do not have symptoms. Two carriers of an autosomal recessive condition have a one-in-four (25%) chance of passing it on to their children.

DNA (deoxyribonucleic acid)—The genetic material that contains the instructions for creating proteins.

DNA base—One unit in a DNA sequence. The four DNA bases are adenine (A), cytosine (C), guanine (G), and thymine (T). The sequence of these bases is the genetic code that contains the instructions for creating proteins.

DNA sequence—The sequence of DNA bases that contains the instructions for creating proteins. A three base sequence in the DNA contains the instructions for making a particular amino acid. For example, CGC codes for the amino acid alanine. Proteins are made up of one or more amino acids strung together. The instructions for a particular protein are made up of a number of three base sequences.

Enzyme—Type of protein that speeds up a chemical reactions that happen in the body.

Gene—A sequence of bases in a DNA sequence that contains the instructions for one protein.

Hyperhomocysteinemia—Increased levels of homocysteine in the blood.

Neural tube defect (NTD)—Severe birth defects in which there is an opening in the skull or spine that exposes the brain or spinal cord. This exposure can result in damage to the brain or spinal cord.

Pathogenic variant—Any change in the sequence of a genome that causes disease.

Variant—Change in the sequence of DNA.

Some more severe and rare variants cause autosomal recessive homocystinuria, a condition associated with high levels of homocysteine. Homocystinuria resulting from MTHFR variants has a childhood or adult onset and

QUESTIONS TO ASK YOUR DOCTOR

- Should I be taking folate?
- What MTHFR gene variant(s) do I have?
- What treatments exist for homocystinuria?

is associated with developmental delay, eye disorders, blood clots, and bone fragility. Carriers of these rare variants do not have homocystinuria but may be at increased risk for blood clots and strokes.

Diagnosis

Genetic testing can identify MTHFR gene variants. Some health providers suggest testing for common MTHFR variants for people with unexplained blood clots. If autosomal recessive homocystinuria is suspected, then urine testing typically shows extremely elevated homocysteine and lower levels of methionine. Sequencing of the whole MTHFR gene to look for and identify variants is recommended since many rare variants can cause this condition. Testing for variants in other genes that can more commonly cause this disorder may also be recommended.

Treatment and management

Supplementation with folate (vitamin B9) and vitamin B6 and B12 may reduce the risk for clots, strokes, and heart disease in some individuals with mild variants such as C677T and A1298C. Women with MTHFR variants who plan to have children, like all women, should take 400 micrograms (mcg) of folic acid each day prior to getting pregnant. This supplementation may decrease the risk of neural tube defects.

People with autosomal recessive homocystinuria caused by MTHFR variants are treated with folate, methionine, and vitamins B6 and B12. They may also be treated with Betaine, a drug that decreases homocysteine levels in the blood. Treatment should be started as early as possible.

Prognosis

Most people with the common and mild C677T and A1298C variants do not have symptoms. Some may have increased risk of heart disease, blood clots, and strokes. This risk may be reduced by folate (vitamin B9) and vitamin B6 and B12 supplements. The risk of neural tube defects may be lower in women with MTHFR variants who take folate prior to pregnancy.

Early treatment of autosomal recessive homocystinuria can prevent symptoms and improve the prognosis. Later treatment cannot reverse symptoms but can make the symptoms milder.

Methylmalonic acidemia

Definition

Methylmalonic acidemia (MMA) is an autosomal recessive disorder that causes defects in metabolism. Individuals who have the disease cannot metabolize vitamin B12. The first recognized cases of MMA were described in 1967. Some non-genetic cases have been reported in which the affected individuals were vegetarians who had been on prolonged cobalamin (vitamin B12) deficient diets.

Description

Methylmalonic acidemia (MMA) is characterized by an accumulation of methylmalonic acid in the blood stream, which leads to an abnormally low pH (high acidity) in nearly every cell in the body (metabolic acidosis). A higher-than-normal accumulation of ketones in the blood stream (ketosis) similar to that seen in instances of diabetes mellitus is also associated with MMA. If left untreated, metabolic acidosis is often fatal.

Methylmalonic acid is an intermediate in the metabolism of fats and proteins. This compound can accumulate in the bodies of individuals with MMA because of a partial or complete inability to convert methylmalonyl-CoA to succinyl-CoA in the tricarboxylic acid (TCA) cycle.

MMA is one of the genetic disorders that affect mitochondrial metabolism. The mitochondria are organelles inside cells that are responsible for energy production and respiration at the cellular level. One of the most important processes in the mitochondria is the TCA, because it produces the majority of the ATP (chemical energy) necessary for maintenance (homeostasis) of the cell. Before glucose enters the TCA cycle, it is broken down into acetyl-CoA, which is then further broken down in the TCA cycle to yield carbon dioxide, water, and ATP. When some fatty acids and certain amino acids from proteins (specifically isoleucine, valine, threonine, methionine, thymine, and uracil) are broken down in preparation to enter the TCA cycle, they provide propionyl-CoA rather than acetyl-CoA. This propionyl-CoA is then converted into methylmalonyl-CoA, which is next converted to succinyl-CoA. It is succinyl-CoA that enters the TCA cycle to eventually yield carbon dioxide, water, and the ATP needed by the cells.

The conversion of methylmalonyl-CoA to succinyl-CoA involves the apoenzyme methylmalonyl-CoA mutase. One of the cofactors required by this apoenzyme is cobalamin (vitamin B12). Genetic MMA is a result of either a deficiency in the methylmalonyl-CoA mutase or a defect in the mechanism inside the cells that converts

dietary vitamin B12 into its useable form for this metabolic reaction.

An enzyme is a chemical that facilitates (catalyzes) the chemical reactions; it is neither a substrate nor a product in the chemical reaction. As a result, enzymes are not used up in chemical reactions, and one molecule of an enzyme may be used to facilitate the same chemical reaction multiple times. All of the enzymes necessary for catalyzing the various reactions of human life are produced within the body by genes. In the case of the enzyme deficiency that causes MMA, the enzyme consists of a genetically produced apoenzyme and a cofactor (vitamin B12) that comes from dietary sources.

Genetic profile

The gene responsible for MMA has been mapped to chromosome 6 in the human genome and is called *MUT*. At least 30 mutations in this gene have been identified that lead to a broad spectrum of clinical symptoms and severities. Approximately 60% of the cases of MMA are due to mutations in the *MUT* gene. Genetic MMA is recessive, meaning that two copies of the mutated gene are required for the disease to present.

Demographics

The exact frequency of MMA is not known. It is believed to occur with a frequency of approximately one in every 48,000 live births in the United States. As in all recessive non-sex linked (autosomal) genetic disorders, both parents must carry the gene mutation in order for their child to have the disorder. Therefore, in cases where the parents are related by blood (consanguineous), the occurrence rate is higher than in the rest of the

Colored transmission electron micrograph (TEM) of tissue showing abnormally shaped and structured mitochondria in the liver. Methylmalonic acidemia is a metabolic disorder that disrupts normal amino acid metabolism. (Patricia M. Zervas, NIH Office of Research Services/Science Source)

population. Parents with one child affected by MMA have a 25% likelihood that their next child will also be affected with MMA.

There is no observed increase in likelihood for the disease on the basis of sex or ethnicity in cases of MMA.

Signs and symptoms

The abnormally high levels of acid in the blood of individuals affected with MMA can produce drowsiness, seizures, and, in severe cases, coma and/or stroke. Prolonged acidemia can cause intellectual disability. In the very rare instances of a complete apoenzyme absence, MMA is associated with sudden infant death syndrome (SIDS) and at least one known case of sudden child death at the age of 11 months.

Dehydration and failure to thrive are generally the first signs of MMA. These symptoms are accompanied by lethargy, lack of muscle tone (hypotonia), and “floppiness” in newborns.

Developmental delay is typically experienced in all individuals affected with MMA if treatment is not started early in life.

Some individuals affected with MMA have facial dysmorphisms. These include a broad nose, a high forehead, a skin fold of the upper eyelid (epicanthal folds), and a lack of the normal groove in the skin between the nose and the upper lip (the philtrum). In a few individuals affected with MMA, skin lesions resulting from yeast infections (candidosis) may be present, particularly in the mouth and facial area. Occasionally, enlargement of the liver (hepatomegaly) is seen in MMA-affected individuals.

When observed in individuals with MMA, uncoordinated muscle movements (choreoathetosis), disordered muscle tone (dystonia), slurred speech (dysarthria), and difficulty swallowing (dysphagia) may be signs of an acidemia-induced stroke.

Diagnosis

In newborns, a history of poor feeding, increasing lethargy, and vomiting are typical symptoms of MMA. In older infants, an episode of lethargy, often accompanied by seizures, is symptomatic. In children or adolescents, the symptoms may include muscle weakness, loss or diminishment of sensation in the legs, and/or blood clots.

Kidney (renal) disease may be observed in affected individuals with long-untreated MMA.

A blood test to detect high levels of methylmalonic acid is a decisive test for MMA. Researchers at

KEY TERMS

Apoenzyme—An enzyme that cannot function without assistance from other molecules called cofactors.

ATP—Adenosine triphosphate. The molecule used by the cells of the body for energy.

Autosomal recessive disorder—A disorder where two copies of a dysfunctional gene must be inherited in order for the trait to present. The gene is present on the non-sex chromosomes.

Cofactor—A substance that is required by an enzyme to perform its function.

Ketosis—An abnormal build-up of compounds called ketones in the blood. This condition usually indicates a problem with blood sugar regulation.

Metabolic acidosis—High acidity (low pH) in the body due to abnormal metabolism, excessive acid intake, or retention in the kidneys.

Methylmalonic acid—An intermediate product formed when certain substances are metabolized.

Sudden infant death syndrome (SIDS)—The unexpected, sudden death of a child under one year of age. Often called “crib death.”

TCA cycle—Formerly known as the Krebs cycle, a process by which glucose and other compounds are broken down into forms that are directly useable as energy in the cells.

the National Institutes of Health (NIH) have developed a breath test (the 1-13C-propionate breath test) that measures how well patients with methylmalonic acidemia (MMA) respond to receiving liver or combined liver and kidney transplantation. The test can also be used to assess the severity of the disease in people and help determine whether they would benefit from surgical or experimental genomic therapies that target the liver. Propionate oxidative capacity, as measured with 1-13C-propionate breath testing, predicts disease severity and clinical outcomes, and it could be used to assess the therapeutic effects of liver-targeted genomic therapies for MMA and related disorders of propionate metabolism. MMA may also be detected via a urine test for abnormally high levels of methylmalonate.

Prenatally, MMA may be diagnosed by measuring the activity of the apoenzyme methylmalonyl-CoA mutase in cultured cells grown from the cells obtained during an amniocentesis.

QUESTIONS TO ASK YOUR DOCTOR

- How is MMA likely to affect my quality of life?
- When should treatment begin for newborns or infants?
- If MMA runs in my family or my spouse's family, what is the chance my children will have the disease?
- What are the side effects of common treatments for MMA?

In one MMA-related case, a woman named Patricia Stallings was sentenced to life imprisonment for the presumed poisoning of her infant son with ethylene glycol, an ingredient in antifreeze. It was not until she gave birth in prison to a second son who was properly diagnosed with MMA that forensic investigators discovered that what was initially thought to be ethylene glycol in her first son's system was, in fact, methylmalonic acid. All charges against Ms. Stallings were dropped, and she was released from prison. This was an extreme case, but it certainly shows the importance of proper medical diagnosis of MMA.

Family history is often used to diagnose MMA when there are affected siblings or siblings who died shortly after birth for unclear reasons.

Treatment and management

Individuals affected with MMA are generally placed on low- or no-protein diets supplemented with carnitine, cobalamin (vitamin B12), and alkalinizing agents such as bicarbonate to neutralize the excess acid caused by MMA. Intravenous administration of glucose may be necessary during acute attacks. In individuals who do not respond to carnitine and/or cobalamin, the anti-bacterial drug metronidazole may be prescribed. This drug kills some of the naturally occurring bacteria in the lower digestive tract and thereby reduces the production of propionate, a precursor chemical to methylmalonic acid. In cases of severe MMA, kidney and/or liver transplants may be called for.

Prognosis

With appropriate care and diet, MMA is a controllable disease that does not kill or permanently disable people beyond the first year of life. If unchecked, MMA can lead to permanent, irreversible disabilities or conditions or even death. Some infants affected with extremely

severe genetic mutations are stillborn or die prior to an appropriate diagnosis of MMA being made.

Microbiome

Definition

The human microbiome refers to the entirety of genetic material of all of the micro-organisms (bacteria,

Illustration of microbiome (gut bacteria), which make chemicals such as dopamine (above) and serotonin (below) that neurons use to communicate with each other. (Carol and Mike Werner/Science Source)

bacteriophage, fungi, protozoa, and viruses) found on or inside the human body. The term was first used by microbiologist Joshua Lederberg in 2001.

Description

There are trillions of microbes living on and inside the human body. In fact, the human body has more microbes than individual cells. According to researcher Dr. Martin J. Blaser at the New York University School of Medicine, “The current estimate is that humans have ten trillion human cells and about 100 trillion bacterial cells.” These organisms conduct necessary functions such as aiding in digestion, protecting from illness, and enhancing the reproductive system. Scientists have known for many years that bacteria play an important role in health. Of the thousands of known bacteria, only approximately 100 are known to be harmful to humans. Using the microbiome, researchers are investigating the role of bacteria and other microbes in promoting and protecting health.

In 2007, researchers at the National Institutes of Health (NIH) began the Human Microbiome Project to study microbiomes within the human body and the genetics of these organisms. Their goal was to “characterize microbial communities found at multiple human body sites and to look for correlations between changes in the microbiome and human health.” This project has led to the discovery of the significance of genetic information from the 10,000-plus different species of microbes that live in and on the human body. It has identified more than eight million unique microbial genes associated with the human microbiome in healthy adults. These microbes contribute more genes used in human survival than the entire human genome. These microorganisms are crucial to human survival, and by studying them, scientists have

recognized the fact the humans need these organisms far more than previously thought. Our microbiome helps us by producing vitamins, controlling our immune system, protecting us against microbes that cause disease, and digesting our food.

Genetic profile

Using several scientific methodologies, researchers have identified some genetic information of the microbiome and how it affects humans. One such method is utilizing the large databases of human genomic data, such as the National Center for Biotechnology Information’s (NCBI) non-redundant Clusters of Orthologous Groups (COG) or the Kyoto Encyclopedia of Genes and Genomes (KEGG) databases and comparing specific sections of the genetics of a micro-organism isolated from the microbiome. The advantage to this method is that it may identify interactions between micro-organisms or between host and micro-organism; however, it is limited because of sections of missing data and gaps in the genome that are not yet identified.

Another method to identify genetic factors of the human microbiome is to use catalogues of known genes within the microbiome. Researchers are compiling data to create more comprehensive catalogues as genes are identified. As technology progresses, scientists expect not only to identify more of the genetics of the microbiome but also to identify more of the significance of micro-organism/host interactions. One such interaction is the AMR gene and antibiotic resistance.

Demographics

Every human, regardless of gender or race, has a microbiome associated with his or her body. There is far more variability within the microbiome than in the human genome, making it an even more individualized set of genetic material. According to Dusko Ehrlich, project coordinator of MetaHIT, a program created to study the genomics of the intestinal tract, “There’s a 0.1% difference in our genomes, but there may be a 50% difference in our metagenome.”

Signs and symptoms

When the microbiome is in balance and working in harmony, there is less chance of illness. However, when the microbiome becomes unbalanced, there is an increased chance of symptoms. The type of symptoms will be determined by the type of imbalance and the part of the body involved. For example, microbe imbalance in the gut can lead to intestinal problems. If the microbe imbalance is present in the respiratory tract, then asthma symptoms may occur. If the bacteria in the gut contain mutations in

antibiotic resistant genes (ARGs), then the body may be susceptible to drug-resistant infections. Other studies have shown a link between changes in the microbiome of the gut and conditions such as obesity and anxiety.

The Microbiome and Disease

Each person's microbiome is unique, and this can influence their health and susceptibility to different

diseases. For example, when our microbiome is not working properly, it can increase our risk of autoimmune diseases like diabetes, arthritis, multiple sclerosis, and muscular dystrophy. Autoimmune diseases occur when your immune system attacks your body by mistake. A faulty microbiome can result in the accumulation of disease-causing microbes, which causes this abnormal immune response. Since we can pass down our microbiome to our children, an

The skin can be thought of as an ecosystem of diverse microorganisms, including bacteria, fungi, viruses, and mites, that live in various creases and sections of body. If the balance gets disrupted, skin disorders or infections can occur. (Science Source)

increased risk for autoimmune diseases may be passed down in families.

The composition of the microbiome influences the development of allergies and asthma, which result from an over-reaction of the immune system. People who have less-diverse microbiomes have fewer species to recognize as foreign but safe, and they are more likely to over-react to allergens. Individuals who have more exposure to microbes tend to have a more diverse microbiome, which can help prevent allergies and asthma. For example, living in a home with dogs seems to increase the diversity of the bacteria in the microbiome and decrease the risk of childhood allergies.

Another condition affected by the microbiome is irritable bowel syndrome (IBS). IBS affects the intestines and causes cramping, bloating, gas, diarrhea, and constipation. The microbiome in the digestive tract can help protect the body from pathogens by producing antibacterial substances like short chain fatty acids (SCFA). IBS patients typically have changes in their gut microbiome. These changes can cause inflammation of the stomach and intestines (gastroenteritis) as the result of a microbe infection. This inflammation can lead to the development of IBS. People with diarrhea-predominant IBS are more likely to have an overgrowth of bacteria in the small intestine. People with constipation-predominant IBS are more likely to have higher levels of microbes that produce methane. Methane gas decreases the contraction of the intestines which can lead to constipation.

The microbiome in the gut appears to affect the functioning of the brain and the nervous system. Research suggests that there is a communication loop between the central and peripheral nervous system and the enteric nervous system (ENS). The ENS controls the function of the gastrointestinal system. This communication is bidirectional, or a loop that links the emotional and cognitive centers of the brain with peripheral digestive functions. The health of your microbiome can, therefore, influence brain and mental health. Changes in the microbiome of IBS patients may contribute to the intestinal pain found in IBS. This is because the microbiome appears to regulate pain in the peripheral and central nervous system. Researchers believe that it may be possible to decrease chronic pain and improve mental and brain health by affecting the gut microbiome through diet and medications.

Large-scale changes of the microbes in the digestive tract and its microbiome appear to be associated with obesity. Changes in digestive tract microbes can alter the metabolism of the host. When that occurs, it may cause inflammation, insulin resistance, and an increase in stored fat. Studies have also found that obese twins may have

Microbiome. Colored scanning electron micrograph (SEM) of bacteria cultured from a fingertip. There are around 1000 species of bacteria from 19 phyla found on human skin. Skin flora is usually non-pathogenic, and either commensal (not harmful to their host) or mutualistic (beneficial). One benefit bacteria can offer is preventing transient pathogenic organisms from colonizing the skin surface, either by competing for nutrients, secreting chemicals against them, or stimulating the skin's immune system. However, resident microbes can cause skin diseases and enter the blood system, creating life-threatening diseases, particularly in immunosuppressed people. (Steve Gschmeissner/Science Source)

fewer types of bacteria in their microbiome and more enzymes that help them more efficiently extract calories. This can lead to more weight gain when consuming less food. Restoration of the microbes in the digestive tract to a healthy state may reduce symptoms and lead to weight loss.

An individual's diet seems to affect the health of their microbiome, which in turn effects the risk of disease. One study found that people who ate more dairy desserts, red meat, and processed foods were more likely to have gut bacteria that were associated with an increased risk of diseases like heart disease and diabetes. Those who ate foods like high-fiber vegetables, nuts, fish, and eggs had gut bacteria that were associated with a lower risk of disease. Processed foods, whether they were plant-based or not, were associated with unhealthier gut bacteria.

A child's exposure to certain chemicals like phthalates, which are found in detergents, plastic clothing, and personal products like shampoo, and polyfluoroalkyl substances, which are found in stain- and water-repellent fabrics, may influence their microbiome. One study found that children with high levels of phthalates in their blood had fewer and less variety of gut bacteria and that

KEY TERMS

Bacteriophage—A virus that can destroy a bacterium.

Metagenome—Genetic material taken directly from an environment.

Microbe—A microorganism.

Microbiota—Microscopic living organisms.

Prebiotic—Chemicals or compounds that induce growth in micro-organisms.

Probiotic—Micro-organisms believed to provide health benefits to humans.

Protozoa—One type of a class of single-celled organism.

Single nucleotide polymorphism (SNP)—A type of single-gene mutation.

those with high levels of phthalates had fewer fungi. A reduction in bacteria and fungi may cause health problems. This study also found that children with higher levels of chemicals in their blood had gut bacteria that are used to clean up toxic chemicals. These types of bacteria are not usually found in the human gut.

The Microbiome and Antibiotic Resistance

The microbiome has also been linked to antibiotic resistance, which happens when bacteria cannot be controlled by antibiotics. The overuse of antibiotics has given rise to many strains of bacteria that are resistant to the antibiotics that are currently available. This is a global threat. These bacteria become resistant through the development of antibiotic resistant genes (ARGs). The human digestive tract is a reservoir of bacteria with ARGs that are resistant to antibiotics. This antibiotic resistance can be passed on to other people. For example, antibiotic resistance can be passed down to a child during birth through exposure to antibiotic resistant bacteria. Interestingly, some research suggests that children born by caesarean section, are more likely to have antibiotic resistance, because they were more exposed to bacteria acquired in the hospital. In this manner, scientists believe that the ARGs that lead to antibiotic resistance are passed from generation to generation. However, a vaginal birth can also expose the child to beneficial bacteria from the mother's microbiome.

Diagnosis

Research into the benefits of the microbiome as a diagnostic tool is ongoing. In 2012, Swedish scientists

showed that the microbial genes in the digestive tract may be a better predictor of risk for developing type 2 diabetes than measurements such as waist-to-hip ratio and body mass index. Also in 2012, researchers from the MetaHIT project presented data to suggest that digestive-tract bacteria were more accurate at predicting obesity and leanness than individual genetic variants. These results have led researchers at the University of Colorado to surmise that microbiomes may help to more accurately diagnose other digestive tract and immune system disorders such as Crohn's disease, which is often misdiagnosed.

Treatment and management

Researchers have discovered that prebiotics and probiotics may help prevent health issues by helping to balance the microbiome. Probiotics are beneficial bacteria, and prebiotics are plant fibers that help feed the healthy bacteria. You can get probiotics from supplements and also from fermented foods like yogurt, sauerkraut, kombucha, and kimchi. Prebiotics can be found in many fruits and vegetables, especially those that contain fiber and resistant starch that your body cannot digest. Some research suggests that prebiotics and probiotics may be effective treatment for some psychological disorders and for digestive disorders such as irritable bowel syndrome (IBS).

Fecal microbiota transplantation (FMT), can also help balance the microbiome. FMT restores the healthy bacteria in the colon by injecting stool into the colon from a healthy donor. FMT can cure often-fatal, drug-resistant infections such as *Clostridium difficile* (*C. difficile*). Antibiotic therapy can upset the balance of the microbiome and allow the *C. difficile* to multiply. The fecal material from the healthy individual, on the other hand, can help to regrow the needed micro-organisms and re-establish a balanced microbiome. This can lead to eradication of the sick bacteria or at least a reduction in its numbers so that symptoms subside. FMT has also been used to treat colitis, constipation, and IBS.

Many researchers think the future of medical treatment may be found in the organisms and genetics of the microbiome. In 2014, a major pharmaceutical company announced a partnership with a biotech company in order to study the microbiome with the goal of developing tests for liver and digestive disease. Other research is seeking to develop small proteins to work with the microbiome to treat conditions like diabetes and autoimmune illnesses. 4D Pharma and Merck are partnering in the development of medicines made up of strains of gut bacteria originally from healthy human donors. These bacteria will be put into capsules and taken orally.

QUESTIONS TO ASK YOUR DOCTOR

- Would I benefit from taking probiotics?
- What, if any, imbalance do I have in the microorganisms in my body?
- Are there tests to perform that can measure the micro-organisms in my body?

Microcephaly

Definition

Microcephaly is a condition in which the size of the skull and the brain is abnormally small. According to the American Academy of Neurology, the specific criterion for microcephaly is a head circumference that is more than two standard deviations below mean size. Some researchers classify severe microcephaly as head circumference that is more than three standard deviations below mean size.

Description

Microcephaly is an abnormally small sized skull and brain. The defect can be the result of hundreds of factors—genetic causes, exposure to alcohol or other drugs, maternal illness during pregnancy, and environment issues—that may affect brain development. Researchers now classify microcephaly as either congenital or postnatal.

Congenital microcephaly is also referred to as primary microcephaly. Other postnatal forms are considered secondary microcephaly.

Microcephaly is often diagnosed in children with cerebral palsy, epilepsy, cognitive impairments, and developmental delays.

Risk factors

Risk factors include maternal exposure to certain illnesses, radiation, or toxins during pregnancy. The condition may also be inherited in an autosomal recessive (carried by both parents) or autosomal dominant (carried by one parent) pattern. This means that a child may inherit it if one or both parents carry the chromosomal defect.

The specific causes of microcephaly are numerous, including:

- Chromosomal. Trisomies 13, 18, and 21
- Degenerative disorders of the mother. Tay-Sachs
- Familial genetics. Autosomal dominant pattern (only one parent carries the gene defect) or autosomal recessive pattern (both parents carry the gene defect)
- Malformations. Lissencephaly, schizencephaly

KEY TERMS

Circumference—The length around a circle.

Encephalitis—Inflammation of the brain.

Lissencephaly—A condition in which the brain lacks folds and is smooth.

Neuroimaging—Imaging studies of the brain, such as x-ray, computed tomography (CT) scans, or magnetic resonance imaging (MRI) scans.

Schizencephaly—A rare disorder caused by abnormal slits within the brain.

Trisomy—Three chromosomes in each cell, rather than two.

- Maternal nervous system infections during pregnancy. Bacterial meningitis (group B *Streptococcus*) or viral encephalitis, herpes virus
- Maternal infections during pregnancy. TORCH complex of maternal infections. TORCH is an acronym for toxoplasmosis, other infections, rubella, cytomegalovirus (CMV), and herpes simplex virus.
- Metabolic disorders of the mother. Phenylketonuria (PKU), maple syrup urine disease
- Placental insufficiency. Toxemia
- Radiation exposure
- Syndromes. Down (most common syndrome cause of microcephaly; 30% of Down syndrome babies have microcephaly), Rubinstein-Taybi, Angelman
- Toxin exposure. Fetal alcohol syndrome, possibly other drugs, such as anticonvulsant medication

In addition to the risk factors listed, scientists believe maternal tobacco smoking as well as uncontrolled or poorly controlled diabetes may cause congenital microcephaly during pregnancy. Older children may develop microcephaly due to lead poisoning or chronic renal failure. It is possible that nearly any chronic disease may contribute to microcephaly.

Genetic profile

Next generation sequencing coupled with whole genome sequencing capabilities have helped to identify genetic loci responsible for primary autosomal recessive microcephaly (MCPH). There have been 13 loci implicated, with mutations in the *ASPM* gene (also known as *MCPH5*) accounting for 25%–50% of diagnosed cases. The second most frequent mutation is in the *WDR62* gene. The identified genes encode for proteins that are essential in cell division and related cellular organelles

such as centrioles and centrosomes. Additionally, these genes encode for proteins involved in cell cycle checkpoints. Mutations in these genes cause improper neural cell division during the development of the cerebral cortex, leading to the reduced skull and brain size.

Demographics

The prevalence of all forms of microcephaly is unknown. The prevalence of all forms of primary microcephaly has been reported to range from 1 in 30,000 to 1 in 250,000 newborns worldwide. Research published in 2014 studying the largest cohort of children diagnosed with primary microcephaly included 680 patients. Of those patients included in the study, the majority were male at 59%, and 41% were female. It is thought that this difference in genders could be attributed to mutations in the X-chromosomal recessive genes, which primarily affect males.

Signs and symptoms

Symptoms of microcephaly include presence of an abnormally undersized skull and brain, usually accompanied by intellectual disability and a reduction in motor capabilities. Impaired muscle control can produce a range of effects from minor clumsiness to major loss of function in the arms and legs. Children can have mildly hyperactive behavior, varying levels of intellectual disability, and may develop seizures as they grow older.

Diagnosis

Examination

The head circumference of a baby is measured at birth. Follow-up measurements are performed during the first three to five years of life. If microcephaly is to be found after birth, most frequently the diagnosis is made by the time the child is two to three years of age.

Head circumference is measured with a measuring tape that is flexible but cannot be stretched. It is placed tightly around the largest portion of the back of the head (occiput) and gently but firmly wrapped around to the front of the head. If the measurement is two standard deviations below normal for the child's age, the measurement's accuracy should be verified, and its plot on the growth chart rechecked.

Tests

If microcephaly is found, imaging studies and genetic testing are performed to attempt to determine the cause. Since children with microcephaly face higher risk for disorders such as cerebral palsy and epilepsy, testing for these conditions should be performed as well.

QUESTIONS TO ASK YOUR DOCTOR

- How small is my baby's head circumference compared to normal size for his or her age?
- What supportive measures can I take to ensure my baby has the best chance for development?
- Is my baby's microcephaly considered congenital or developed?
- What do you think caused my baby to have microcephaly?
- What is my risk for giving birth to another child with microcephaly?

Procedures

Microcephaly may be diagnosed prior to birth, during a sonography (ultrasound) procedure in the latter stages of pregnancy.

Babies may undergo magnetic resonance imaging (MRI) studies to determine brain size and check for abnormalities in the brain.

Treatment and management

Treatment for primary microcephaly is supportive. Neuroimaging is important in treating babies with microcephaly to help determine the extent of the disorder. In secondary or postnatal microcephaly there may be the option to surgically open parts of the skull that have closed prematurely to allow continued growth of the brain tissue. Microcephaly may develop if the fetus is exposed to a number of infections or toxic substances. Avoiding alcohol, recreational drugs, and possibly certain medications, as well as maintaining optimum health during pregnancy are steps that a mother can take to lower her chances of giving birth to a child with microcephaly. Infections also play a role, and it is important for the pregnant woman to take steps to minimize her chance of acquiring infection. For example, toxoplasmosis is one potential cause of microcephaly, and may be transmitted in feline feces; therefore, pregnant women should not clean feline litter boxes.

If it is suspected that the gene may be present in either the mother or the father, genetic counseling is recommended.

Proper prenatal health care is essential to ensuring that, if health problems arise, they will be appropriately managed.

Prognosis

About 20%–30% of infants with severe microcephaly will die. Those who survive have a prognosis that includes intellectual deficiency, developmental delays, neurological disorders such as epilepsy, and intellectual disability. Treatment is supportive. Those patients that are candidates for surgical correction of the skull typically have a better prognosis.

Genetic counseling is recommended for families who have a case of microcephaly within the family.

Microcephaly and hypomyelination

Definition

Microcephaly can be congenital or can develop over the first two years of life. Microcephaly also can be a component of different conditions that cause brain growth defects.

Hypomyelination is a neurological disorder that is present at birth and is characterized by a loss of the fatty insulation around neurons.

Both conditions may be present as additional symptoms of other developmental or neurological syndromes.

Description

Microcephaly

Microcephaly means “small head” and is a neurodevelopmental disorder defined by a head circumference that is two to three standard deviations below the mean for age and gender. There are two types of microcephaly based on its onset:

- Congenital microcephaly—present before birth
- Postnatal microcephaly—develops after birth

Both forms of the disease result from the brain not developing normally, either in utero or after birth. There are genetic and environmental factors that contribute to the causes of microcephaly. A small head characterizes the disorder, but the facial features continue to develop normally, giving the individual disproportionate features. During infancy the bones of the skull can fuse too early and limit the size and shape of the skull; this can have an impact on brain development, as the smaller skull doesn't grow along with the brain. Individuals with microcephaly are often short in stature and have limited or low intelligence.

In the nineteenth and twentieth centuries in North America and Europe, people with microcephaly were sold to freak shows and circuses, where they were known as “pin heads” and sometimes presented as different species.

Hypomyelination/CHN

Hypomyelination is an inherited disease that affects the nervous system and sometimes also affects the eyes. Congenital hypomyelination neuropathy (CHN) presents at birth and involves defects in white matter in the brain, where the nerves lose or lack the myelin sheathing from around the axons. This leads to a breakdown in nerve impulses, causing lost or impaired feeling and movement, muscle weakness, and respiratory difficulties.

Genetic profile

Microcephaly

Congenital microcephaly develops before birth and can be inherited several different ways; it can be a familial autosomal recessive or dominant inherited trait, it can be X-linked, or it can be due to chromosomal balanced rearrangements. These are considered isolated events of

KEY TERMS

Cataracts—A cloudy disruption of the eye lens that affects sight due to protein deposits in the lens.

Chromosomal abnormality—When chromosomes are missing or extra chromosomes are present.

Congenital—Occurring at or before birth.

Craniosynostosis—A rare skull abnormality that causes the bones of the skull to be deformed or not develop normally.

Leukocephalopathies—Defects in the white matter of the brain.

Myelin—The fatty protein that insulates the axons of nerve cells and helps maintain the fidelity of nerve impulses.

White matter—Part of the central nervous system found in the brain and superficial spinal cord. It is made mostly of myelin-covered nerve cells that send signals from one region of the cerebrum to another. The name comes from the myelinated nerve cells, which are white in color.

the disorder. Non-genetic events that can contribute to acquired forms of the disorder are caused by disruptive injuries like stroke or congenital infections like rubella. Microcephaly is also sometimes seen in infants born with fetal alcohol syndrome. Maternal malnutrition can also contribute to microcephaly development in children.

In postnatal onset of microcephaly, metabolic disorders can cause abnormal development after birth. Mitochondrial and peroxisomal disorders are common examples of metabolic defects that lead to microcephaly.

The microcephalin gene (*MCPH1*) causes primary microcephaly when the mutation is homozygous. *MCPH1* is expressed in the brain and can affect the development of several different regions during fetus growth.

Hypomyelination/CHN

CHN is a congenital autosomal recessive disease that can present mild to severe phenotypes and is characterized by the recurrent loss and repair of myelin due to mutations in genes required for myelin formation. The exact cause of CHN is not well described, and the loss of myelin is not understood. Along with the inability to make myelin, CHN patients are also often born with cataracts.

Children born with CHN usually develop normally in their first year of life and then slowly start losing their ability to move on their own.

The *FAM126A* gene has been implicated in CHN. *FAM126A* encodes the protein hyccin, which is thought to function in myelin production. It is expressed in the cells of the nervous system and the cornea of the eye. Severity of CHN might depend on the type of mutation in *FAM126A* and whether the protein function is only partially or completely lost.

Recently, mutations in the gene *PYCR2* (pyrroline-5-carboxylate reductase 2) were shown to cause both microcephaly and hypomyelination. *PYCR2* is involved in proline biosynthesis, and the mutation displays a unique syndrome that includes both congenital microcephaly and reduced white matter in the brain due to hypomyelination.

Demographics

In most cases of microcephaly and CHN, both female and male children are affected equally. CHN is exceptionally rare, but can affect both sexes.

Signs and symptoms

Microcephaly

In newborns, neurological defects and seizures are common, as well as intellectual developmental delays. In some cases, infants can be born with normal or reduced head size, but then their head fails to grow as the rest of their body develops. As the child grows, the smallness of the skull will become more pronounced. This can lead to a receding forehead and loose scalp as the face continues to grow at a normal rate. Some individuals will also be short in stature, their motor function and speech can be delayed, and hyperactivity and mental disability are common to varying degrees.

Depending on the cause and the extent of the additional symptoms associated with microcephaly, the overall presentation of the disorder can vary. Some people develop normally with normal levels of intelligence; others can be mentally and physically disabled.

Hypomyelination/CHN

Signs and symptoms may vary depending on the extent of the effects of the disease. Major symptoms include delayed motor development, weakened muscles, impaired coordination, and difficulties breathing and swallowing.

Diagnosis

Microcephaly

Family histories can be taken to determine the chances of a child being born with microcephaly or one

QUESTIONS TO ASK YOUR DOCTOR

- What is the most likely cause of these syndromes?
- What additional testing or special treatments are available for my specific case?
- What are the chances that my other children will develop these syndromes?

of the other syndromes that include microcephaly as a symptom. Physical exams and head circumference measurements can be made at birth and during development to track the progression of the disorder. CT and MRI scans and blood tests can be used to better understand other underlying causes.

Hypomyelination/CHN

To test for CHN, an electromyogram can be used to measure the speed of electrical impulses produced by muscle, which will give some information about the function of neurons. Poorly myelinated neurons will have slower impulse measurements than those that are well insulated. Nerve and muscle biopsies can be taken to observe the physiology of the cells on a histological level.

Treatment and management

Microcephaly

In some cases of craniosynostosis, surgery can be used to separate the bones of the skull and make room for the brain to grow. In most cases, speech and occupational therapies are used to improve quality of life for patients.

Hypomyelination/CHN

There are no good treatment plans for individuals with CHN. Most treatment is supportive and seeks to improve the quality of life in CHN patients.

Microcephaly with spastic diplegia

Definition

Microcephaly with spastic diplegia, also known as Paine syndrome, is a rare genetic condition that is present at birth. Characterized by an undersized head and related abnormalities in the brain, the disease results in severe intellectual disability and physical retardation, movement disorders, and vision problems. Most infants with microcephaly with spastic diplegia do not survive their first year of life.

Description

The cerebellum (Latin for “little brain”) is the part of the brain that controls involuntary movements, such as maintaining balance and coordinating muscles during physical activity. When shaking hands, for example, the cerebellum plays a primary role in coordinating the dozens of muscles involved in this seemingly simple task. Microcephaly with spastic diplegia interferes with the proper growth of the cerebellum and other parts of the brain while the fetus is still in the womb. Though this syndrome is considered a single entity, it actually includes several disorders that emerge together. The result is a variety of debilitating effects.

Microcephaly, which is characterized by an abnormally small head, is a neurological disease that is associated with several conditions. The head of an infant with

KEY TERMS

Amino acids—Organic compounds that form the building blocks of protein. There are 20 types of amino acids (8 are “essential amino acids” that the body cannot make that and must be obtained from food).

Congenital—Refers to a disorder that is present at birth.

Gavage—Administration of food via a feeding tube to the stomach.

Neurological—Relating to the brain and central nervous system.

microcephaly is smaller than average when compared to other babies of the same age and gender. This decreased skull size is an indication that the brain did not grow properly during fetal development. The form of microcephaly associated with microcephaly with spastic diplegia causes physical retardation and intellectual disability. Aside from a small head, infants with microcephaly with spastic diplegia may have undersized bodies. Motor skills, language abilities, and other aspects of normal development are impaired. Babies with microcephaly with spastic diplegia, for example, may require a gavage due to feeding difficulties or trouble swallowing. Unlike most infants, they may seem disinterested in the world around them.

Microcephaly with spastic diplegia also produces specific problems related to movement. Infants affected by the disease develop spasticity. This nervous system disorder, in which muscles do not relax properly after being stretched, can cause muscle stiffness, pain, or physical deformity. It can also lead to repetitive spasms by a particular muscle or group of muscles (these spasms are known as myoclonic jerks). Aside from spasticity, an infant with microcephaly with spastic diplegia may experience generalized seizures.

Vision can also be affected, resulting in optic atrophy. This eye disorder causes a degeneration of the nerves carrying information from the eyes to the brain. Optic atrophy can lead to blurry vision or other visual disturbances.

The underlying cause of microcephaly with spastic diplegia is unknown. The effects of the disease are thought to stem from the limited growth of the cerebellum and other areas of the brain. Autopsies of affected children have revealed underdevelopment of this region, as well as abnormalities in the cerebrum and other brain structures.

QUESTIONS TO ASK YOUR DOCTOR

- What physical conditions make microcephaly with spastic diplegia such a serious medical disorder?
- What information and advice can a genetic counselor provide about the possibility of our child's being born with microcephaly with spastic diplegia?
- Are there prenatal tests available for microcephaly with spastic diplegia?

Microcephaly with spastic diplegia is considered very similar to another genetic, congenital disease known as Seemanova syndrome. Both diseases have a number of symptoms in common, although Seemanova syndrome lacks certain characteristics of the former (such as an underdeveloped cerebellum). Some doctors view both conditions as variations of a more broadly defined disorder called Paine-Seemanova syndrome.

Genetic profile

The gene responsible for microcephaly with spastic diplegia has not been identified, but it is believed to lie on the X chromosome. For this reason, the disease is referred to as an X-linked genetic condition. Only males are affected. Females do not usually develop the symptoms of microcephaly with spastic diplegia, but they may be carriers of the gene associated with the disease. This is because women have two X chromosomes, while men only possess one. Even if a woman possesses the gene for microcephaly with spastic diplegia on one of her X chromosomes, she still has a second X chromosome that is free of the faulty gene. This second X chromosome is what protects her from developing symptoms of microcephaly with spastic diplegia, although she may be able to transmit the disease to her children.

Demographics

Microcephaly with spastic diplegia is a rare, congenital disease that only affects males. Most children born with it do not survive infancy.

Signs and symptoms

The most visible symptom of microcephaly with spastic diplegia is often the size of the head, which is smaller than normal. Affected infants may experience feeding difficulties or swallowing problems. They may

not appear to be growing properly, or they may seem disinterested in their environment. The development of motor skills and speech is delayed.

In simple terms, microcephaly with spastic diplegia causes structural abnormalities in the cerebellum, cerebrum, and other parts of the brain. The skull itself is abnormally small due to the fact that its size is dictated by brain growth. Damage to the optic nerve may also occur. In addition, microcephaly with spastic diplegia produces elevated amino acid levels in the urine and cerebrospinal fluid.

Diagnosis

Microcephaly with spastic diplegia is often diagnosed at birth when the size of the head is measured, although a small head circumference may be identified later during a routine exam if it is not detected shortly after delivery. Imaging procedures (such as an x-ray, CT scan, or MRI) are used to identify the structural abnormalities of the brain and skull. Analyses of blood and urine are also performed. An electroencephalogram (EEG), a non-invasive test that measures the electrical activity of the brain, may be recommended to help assess developmental problems or detect relevant brain or nervous system abnormalities.

Treatment and management

There is no cure for microcephaly with spastic diplegia. The changes in brain structure associated with the disease cannot be reversed. When possible, treatment focuses on alleviating symptoms. Anticonvulsants, for example, can be used to help control seizures; dextroamphetamine may also be prescribed to ease symptoms. In addition to drugs, orthopedic surgery is sometimes necessary. Family education and genetic counseling for parents is also recommended.

Prognosis

Due to its debilitating effects on the brain and nervous system, microcephaly with spastic diplegia is usually fatal within one year after birth.

Microdeletion and microdeletion syndromes

Definitions

Microdeletions are losses of genetic material from chromosomes that are too small to detect by karyotyping, which remains the standard cytogenetic procedure for identifying the complete set of chromosomes in an individual organism and detecting any abnormalities in the number or structure of the chromosomes. In regard to chromosomal deletions, karyotyping generally cannot detect deletions smaller than 5 mega bases (5 million base pairs). These smaller deletions (usually of several contiguous genes) are called microdeletions.

The significance of microdeletions for human health is that while some of these aberrations have no known effects on growth or development, others cause genetic disorders collectively known as microdeletion syndromes. Microdeletions on the long arm of the Y chromosome are associated with infertility in about 20% of men diagnosed with low sperm count.

A similar abnormality in which a small segment of a chromosome is doubled is called a microduplication. The significance of microduplication syndromes is less well defined as of 2021 than for microdeletion syndromes, partly because the symptoms of microduplication syndromes are less severe in most cases. Although both types of syndromes are sometimes called contiguous gene syndromes or CGSs, researchers prefer to refer to the two types separately.

Both microdeletions and microduplications are examples of copy number variations or CNVs. Microdeletions represent copy number losses, and microduplications represent copy number gains.

Fluorescence in situ hybridization (FISH) micrograph of human chromosomes showing Williams syndrome, a genetic disorder is caused by the deletion of a gene on chromosome 7. The chromosome marked 7 at lower right shows four dots (genes) at the corners of its lower half (green). The chromosome marked del(7) at upper left shows only one such green area. (Addenbrookes Hospital/Science Source)

Description

The basic cause of microdeletions as well as of other chromosome abnormalities is the instability of the human genome itself. There are a large number of repetitive elements in the genome that can be either lost or duplicated during the process of cell division or the recombination of chromosomes that occurs during meiosis. Most microdeletions occur during the formation of gametes (sperm or eggs). The loss of genetic material that characterizes microdeletions can occur as a result of unequal crossover between a pair of chromosomes or as a result of chromosomes breaking apart without rejoining.

Unlike some other chromosomal aberrations, microdeletions do not have any known connection to maternal age, which means that younger women can give birth to children with microdeletion syndromes. Microdeletions are thought to be sporadic (random) occurrences known as *de novo* mutations. In some cases, however, the discovery of a microdeletion syndrome in a child may lead to the parents being tested and found to have the same microdeletion but with milder effects.

Genetic profiles

The number of identified microdeletion syndromes continues to increase with the advent of sophisticated diagnostic assays and next-generation sequencing (NGS) technology, which allow researchers to focus on very small segments of chromosomal DNA throughout the human genome. The Genetic and Rare Diseases Information

Center (GARD) of the National Institutes of Health lists 62 microdeletion syndromes; the National Organization for Rare Disorders (NORD) lists 41; a paper published in 2012 lists no fewer than 211 microdeletion syndromes, and the number has risen to over 300 as of 2021. The following is a list of the better-known microdeletion syndromes and their genetic profiles:

- Alagille syndrome: microdeletion at chromosome 20p12, causing a loss of the *JAG1* gene.
- Angelman syndrome: microdeletion at 15q11 on the mother's chromosome 15, causing a loss of the *UBE3A* gene.
- DiGeorge syndrome: microdeletion at 22q11.2, causing the loss of 30 to 40 genes.
- Langer-Giedion syndrome: microdeletion at 8q24.1, causing the loss of the *TRPS1* and *EXT1* genes.
- Miller-Dieker syndrome: microdeletion at 17p13.3, causing the loss of the *PAFAH1B1* and *YWHAE* genes.
- Prader-Willi syndrome: microdeletion at 15q11 on the father's chromosome 15.
- Rubinstein-Taybi syndrome: microdeletion at 16p13.3, leading to the loss of either the *CREBBP* or the *EP300* gene.
- Smith-Magenis syndrome: microdeletion at 17p11.2, leading to the loss of the *RAI1* gene.
- Williams syndrome (also called Williams-Beuren syndrome): microdeletion at 7q11.23, causing the loss of more than 25 genes.

Demographics

The prevalence of microdeletion syndromes vary widely; some are extremely rare:

- Alagille syndrome: 1 in every 30,000 to 1 in every 40,000 persons.
- Angelman syndrome: 1 in 12,000 to 1 in 20,000 persons.
- DiGeorge syndrome: 1 person in 4,000.
- Langer-Giedion syndrome: very rare; about 60 cases reported worldwide, with males affected three times as often as females.
- Miller-Dieker syndrome: fewer than 1 person in every 100,000.
- Prader-Willi syndrome: 1 in 10,000 to 1 in 30,000 persons.
- Rubinstein-Taybi syndrome: 1 in 250,000 to 1 in 300,000 persons.
- Smith-Magenis syndrome: 1 in 15,000 to 1 in 25,000 persons.
- Williams syndrome: 1 in 7,500 to 1 in 20,000 persons.

Signs and symptoms

- Alagille syndrome: liver problems leading to eventual liver failure; failure to thrive; structural abnormalities of the heart; skeletal abnormalities; abnormal band within the cornea of the eye.
- Angelman syndrome: small head with characteristic facial features; severe intellectual disability, movement problems, seizures, and sleep disorders.
- DiGeorge syndrome: heart problems, characteristic facial features, developmental delays, cleft palate, learning difficulties, and psychiatric issues.
- Langer-Giedion syndrome: Sparse scalp hair, hearing loss, intellectual disability, short stature, and skeletal abnormalities.
- Miller-Dieker syndrome: lissencephaly (smooth brain without the usual grooves and ridges); short upturned nose, small jaw, widely spaced eyes; growth retardation, intellectual disability, epilepsy, feeding difficulties.
- Prader-Willi syndrome: weak muscles, mild intellectual impairment; ravenous appetite leading to obesity and type 2 diabetes; inability to have children.
- Rubinstein-Taybi syndrome: short stature, small head, broad thumbs and broad first toes; learning difficulties; delayed bone growth.
- Smith-Magenis syndrome: intellectual disability; abnormal facial features; behavioral problems including self-harm and temper tantrums; sleeping difficulties.
- Williams syndrome: mild-to-moderate intellectual disability; dental problems; heart defects; high levels of blood calcium.

Diagnosis

Some microdeletions can be detected by prenatal testing, but others—particularly the rare types—are identified after the child is born and develops the symptoms of a microdeletion syndrome. As standard karyotyping will not identify microdeletions, several techniques have been introduced since the early 2000s to assist in diagnosing microdeletion syndromes.

A noninvasive prenatal screening test known as NIPS or NIPT uses cell-free fetal DNA (cffDNA) that is released from cells in the placenta and circulates in the expectant mother's blood after the ninth or tenth week of pregnancy. The test is considered noninvasive, because it requires only a simple blood draw from a vein in the arm and poses no risk to the pregnancy. NIPT is designed to screen for some of the more common chromosomal disorders, including trisomies, abnormalities of the sex chromosomes, and several microdeletion syndromes (Angelman, DiGeorge, and Prader-Willi syndromes). NIPT is not a diagnostic test in the strict sense and must

be followed up by invasive tests like amniocentesis or chorionic villus sampling if the screening test indicates the presence of a chromosomal abnormality.

Cytogenetic techniques that have been developed to identify microdeletions in a person's genome include:

- **Fluorescence in situ hybridization (FISH).** FISH is a technique for detecting and identifying a specific sequence of DNA on a chromosome. The researcher designs a probe, which is a small DNA sequence that contains a fluorescent molecule. The probe then binds to its corresponding sequence on the chromosome being tested. FISH is now considered an older method for identifying microdeletions.
- **Array-based comparative genomic hybridization (array CGH).** Also called chromosomal microarray analysis or CMA, this test was introduced in 2005 and is most often used to identify microdeletion syndromes associated with developmental delays. The researcher takes a DNA sample from the blood of the affected person and a reference blood sample from a healthy subject. The DNA samples are then labeled with two different fluorescent substances, usually red for the control (normal) DNA and green for the DNA to be tested. The labeled DNA samples are mixed and allowed to bind (hybridize) to short fragments of synthetic DNA known as probes on the surface of the array (a glass or plastic chip). If the test DNA contains the microdeletion of interest, it will not bind correctly to the probes on the chip that represent the normal DNA sequence; it will instead bind to the sequence on the chip that represents the mutated DNA.
- **BACs-on-beads (BoBs)** is a newer assay used since 2014 to identify microdeletions during pregnancy. The BoBs assay is a bead-based multiplex assay using polystyrene beads impregnated with two different infrared fluorochromes (fluorescent chemical compounds). The DNA to be tested is derived from amniotic fluid or chorionic villus material taken from the expectant mother. The test DNA and reference DNA from a healthy subject are then hybridized onto the polystyrene beads. After washing, the beads are scanned with a microarray scanner to generate images for analysis. The BoBs assay can be used to identify Williams-Beuren, Miller-Dieker, Smith-Magenis, and Langer-Giedion microdeletion syndromes as well as DiGeorge, Angelman, and Prader-Willi syndromes.

Treatment and management

Treatment and management of microdeletion syndromes vary widely, depending on the patient's symptoms and their severity.

- **Alagille syndrome:** symptoms vary greatly in severity, ranging from minor digestive complaints to the need for heart or liver transplants. Some people with the syndrome may need treatment from a variety of specialists, including cardiologists, gastroenterologists, nephrologists, and ophthalmologists; others may not need any specialized treatment.
- **Angelman syndrome:** There is no cure for the syndrome; treatment is primarily supportive, with antiseizure medications and physical therapy.
- **DiGeorge syndrome:** Symptoms vary considerably in type and severity, even among members of the same family.
- **Langer-Giedion syndrome:** Some treatments are available for the hearing loss and facial abnormalities.
- **Miller-Dieker syndrome:** There are no effective treatments for the lissencephaly; few patients live past age 2.
- **Prader-Willi syndrome:** A strict diet and exercise program is needed to control weight; growth hormone is usually beneficial; counseling and medications are required for the behavioral issues. People with Prader-Willi syndrome typically need to live in group homes in adult life.
- **Rubinstein-Taybi syndrome:** There is no treatment that can reverse or cure the syndrome. Patients are usually referred to specialists for treatment of their specific symptoms.
- **Smith-Magenis syndrome:** Supportive treatment, including physical therapy, occupational therapy, and behavioral therapy, is required throughout the patient's lifetime. Medications may be needed to control the psychiatric symptoms.
- **Williams syndrome:** There is no cure for this syndrome, although avoiding extra calcium and vitamin D, and treating high blood calcium levels are helpful. Children and adolescents also benefit from social skills training and behavioral therapy.

Prognosis

- **Alagille syndrome:** Affected persons with severe heart or liver problems have a shortened lifespan, rarely reaching 40 years of age. Those who are less severely affected have a normal life expectancy.
- **Angelman syndrome:** In many patients, the symptoms improve with age; however, life expectancy is usually shortened by 10 to 15 years.
- **DiGeorge syndrome:** Life expectancy is shortened in patients with severe heart defects and/or severe immune system problems. In addition, patients have an increased risk of developing schizophrenia.

KEY TERMS

Aneuploidy—An abnormal number of chromosomes in a cell, whether extra or missing chromosomes.

Assay—A laboratory test designed to identify and measure the amount of a specific substance.

Autosome—Any chromosome that is not a sex chromosome. The human genome has 22 pairs of autosomes.

Base pair (bp)—Any of the complementary nucleotide bases (adenine-thymine and cytosine-guanine in DNA; adenine-uracil and cytosine-guanine in RNA) held together by weak hydrogen bonds. Base pairs form links between the two strands of DNA.

Carrier—In genetics, a person who has a genetic mutation associated with a disease and is capable of passing it on. A carrier may or may not display the symptoms of the disease.

Chromosome aberrations—A general term for abnormalities in either the number or the structure of chromosomes.

Contiguous gene syndrome (CGS)—An older term for microdeletion syndromes in which several genes lying closely together on the chromosome are lost as a group.

Copy number variation (CNV)—A difference in the number of copies of a gene (normally two) or of a specific segment of DNA.

Cytogenetics—The branch of genetics that studies the components of a cell associated with heredity, particularly the chromosomes.

De novo mutation—A genetic variant that occurs in a child but is not present in either parent.

Fluorescence in situ hybridization (FISH)—A laboratory technique for detecting and identifying a specific sequence of DNA on a chromosome. The researcher designs a probe, which is a small DNA sequence that contains a fluorescent molecule. The probe then binds to its corresponding sequence on the chromosome.

Genome—The total amount of genetic information within an organism's chromosomes, including its genes and DNA sequences.

Karyotype—The complete set of chromosomes in a species or individual organism. The term can also

refer to the laboratory technique used to produce an image of an individual's chromosomes.

Mega base pairs (Mbp)—A million base pairs.

Meiosis (pronounced my-OH-sis)—The process of cell division during the production of ova and sperm, in which the material in the chromosomes undergoes recombination (first-stage meiosis), and the chromosomes are reduced to a single set of 23 instead of the normal number of 23 pairs (second-stage meiosis).

Microdeletion—A chromosome deletion that is too small to be detected by standard karyotyping methods. Microdeletions are typically 1 to 3 mega bases in length (1 to 3 million base pairs), whereas standard deletions are 5 mega bases or longer.

Microduplication—The abnormal doubling of a small segment of a chromosome that is too small to be detected by standard karyotyping.

Next-generation sequencing—A general term for massively parallel sequencing of large portions of DNA base pairs, performed by first fragmenting the DNA, reading the individual fragments in parallel, and then reassembling the reads to obtain the sequence of the entire genome.

Noninvasive prenatal testing (NIPT)—A blood test administered to a pregnant woman to screen for an abnormal number of chromosomes (aneuploidy) in the developing fetus. It is also known as noninvasive prenatal screening or NIPS.

Single nucleotide polymorphism (SNP)—A germline substitution of a single nucleotide (any of a group of molecules that form the building blocks of DNA or RNA) at a specific position in a person's genome.

Trisomy—A type of aneuploidy in which there are three copies of a specific chromosome in cells instead of the normal two. Genetic disorders caused by trisomies include Down syndrome (trisomy 21) and Edwards syndrome (trisomy 18).

Y chromosome—The sex chromosome (allosome) that is found together with an X chromosome in normal human males. Microdeletions in the Y chromosome can affect a man's fertility in adult life.

QUESTIONS TO ASK YOUR DOCTOR

- Have you ever treated a patient with a microdeletion syndrome?
 - If so, how was the disorder diagnosed?
 - Because younger women can give birth to children with microdeletion syndromes, would you advise such women to undergo prenatal screening or testing for these disorders?
 - Have you ever referred a patient for FISH or CMA testing?
- Langer-Giedion syndrome: People with Langer-Giedion syndrome usually have a normal life expectancy.
 - Miller-Dieker syndrome: Death in childhood is the most common outcome; the oldest known individual with this syndrome died at the age of 17.
 - Prader-Willi syndrome: Patients usually have a normal life expectancy, provided they do not become extremely obese.
 - Rubinstein-Taybi syndrome: Life expectancy is usually not affected except in patients with severe heart defects. Patients are, however, at increased risk of developing cancer in adult life.
 - Smith-Magenis syndrome: Affected people usually have a normal life expectancy.
 - Williams syndrome: Patients suffer from high blood pressure throughout life; life expectancy is shortened by the increased risk of heart disease.

Rebecca J. Frey, PhD

Microphthalmia with linear skin defects

Definition

Microphthalmia with linear skin defects (MLS) is a rare genetic disorder that causes abnormalities of the eyes and skin. This disorder was first recognized as a distinct genetic condition in 1990.

Description

MLS is a rare disorder that is observed only in females because males with the disease do not survive to birth. This disorder is also called MIDAS (microphthalmia, dermal aplasia, and sclerocornea) syndrome. People affected by MLS have the following:

- small sunken eyes (microphthalmia)
- irregular red streaks of skin on the head and neck (skin erythema)
- abnormal development of the sclera and cornea of the eye

The eye is composed of three layers: the sclera, the choroid, and the retina. The sclera is the tough white outer coat of the eyeball. As this coat passes over the lens,

KEY TERMS

Cornea—The transparent structure of the eye over the lens that is continuous with the sclera in forming the outermost, protective layer of the eye.

De novo mutation—A genetic mutation that is seen for the first time in the affected person, not inherited from the parents.

Microphthalmia—Small or underdeveloped eyes.

Orbital cysts—Small fluid-filled sacs that abnormally develop inside the bony cavity of the skull that holds the eyeball.

Sclera—The tough white membrane that forms the outer layer of the eyeball.

Septum pellucidum—A membrane between two of the normal cavities of the brain that prevents electrical signals from passing between different portions of the brain.

Skin erythema—Irregular red streaks of skin.

Terminal deletion—The abnormal early termination of a chromosome caused by the deletion of one of its ends.

it normally becomes clear. This clear portion of the sclera is the cornea. Both the sclera and the cornea are affected by MLS.

The choroid is the middle layer of the eye. It serves to nourish the retina and absorb scattered light. The retina is the inner, light-sensitive layer of the eye. The retina receives the image transmitted by the lens, and it contains the rods and cones that are responsible for color vision and vision in dim light. Both the choroid and the retina are unaffected by MLS.

Genetic profile

The gene responsible for the signs and symptoms of MLS has been localized to a portion of the short arm (p) of the X chromosome Xp22.3. The specific symptoms of MLS are believed to result from a *de novo* premature cutoff (terminal deletion) of an X chromosome, which, in most cases, deletes the *HCCS* gene, the *MID1* gene, and a portion of the *ARHGAP6* gene, all of which play a role in the development of the eye. People with MLS do not have the portion of the short arm of the X chromosome beyond the Xp22.2 location.

The *HCCS* gene deletion is the primary gene deletion known to cause the signs and symptoms of the condition. This gene encodes for an enzyme known as holocytochrome c-type synthase enzyme, which functions in the

Microphthalmia with linear skin defects: pedigree analysis chart (Gale)

developing embryo within the mitochondria of cells, which are the energy-producing organelles of the cell. Damage to the mitochondria typically leads to cell death or at least moderate to severe cell impairment.

Nearly all of the cases of MLS are believed to result from *de novo* mutations, since parents of affected individuals do not carry the MLS mutation in their chromosomes. A *de novo* mutation is caused by a problem with the chromosomes of the parental egg or sperm cells. The remainder of the chromosomes in the parents is not affected. As the sex cells of one of the parents reproduce, an error occurs. This leads to the transmission of a new mutation from that parent to his or her child. This mutation is expressed for the first time in the child of that parent.

A typical female has two X chromosomes. A typical male has one X chromosome and one Y chromosome. Because no XY male has ever been diagnosed with MLS, it is assumed that MLS is dominant and X-linked with 100% fetal mortality in males. This type of genetic disorder is also called an X-linked male-lethal trait.

There have been a few reported cases of males affected with MLS. These individuals presumably

survived because they were XXY males (genetically female with ambiguous or male sex organs), rather than the typical male with XY chromosomes. This condition (XXY) is called Klinefelter syndrome.

Demographics

Approximately 300 individuals, all without a Y chromosome, have been diagnosed with MLS worldwide. MLS is not associated with any particular sub-populations. It appears with equal frequency in all races and across all geographies. Because it is an X-linked male-lethal trait, it is observed exclusively in females or, in a few cases, in XXY males.

Signs and symptoms

MLS is characterized by the following:

- small, sunken eyes (microphthalmia)
- defects of the sclera and cornea portions of the eye
- linear red streaking of the skin on the upper body, primarily the head and neck
- abnormal protrusion of the abdominal contents upward through an opening in the diaphragm (diaphragmatic

QUESTIONS TO ASK YOUR DOCTOR

- How often should I be examined for visual changes?
- What are my treatment options?
- What are the chances my future children will inherit this disease?
- Should my family members be tested for carrying the disorder?

hernia), which causes difficulty with breathing (respiratory distress)

- a lack of the transparent membrane (septum pellucidum) in the brain that forms a wall between two of the normal cavities (the lateral ventricles) of the brain
- a condition in which the heart is located on the right side rather than the left side of the chest (dextrocardia)

In individuals affected with MLS, the bony cavity that contains the eyeball (orbit) often contains small fluid-filled sacs (orbital cysts). The sclera is often not fully or properly formed, and the cornea generally has areas that are opaque rather than transparent. This corneal opacity causes blurring of vision and may result in blindness. Corneal opacities should not be confused with cataracts, which are opacities of the lens of the eye, not of the cornea.

Difficulty in breathing (respiratory distress) is seen at birth in some patients with MLS. This is caused by a hole in the muscle beneath the lungs (diaphragm) that is responsible for the flow of air into and out of the lungs. This condition will rapidly lead to death if it is not surgically repaired.

Seizures and intellectual disability have been observed in some MLS patients. It is believed that these individuals do not have a septum pellucidum. The absence of this membrane may allow electrical transmissions between parts of the brain that are usually isolated from each other. These inadvertent electrical signals may cause the seizures and the intellectual disability. Developmental symptoms that may be present in patients with MLS include growth delay and/or retardation, heart defects, hernias, auricular malformations, and/or genitourinary malformations.

Diagnosis

MLS is generally diagnosed by the presence of the characteristic red striping of the skin on the head and

neck accompanied by small eyes (microphthalmia) and opaque patches on the corneas.

MLS is differentiated from Goltz syndrome, which has a similar gene locus, in that the patient with MLS has skin irregularities only on the upper half of the body, most typically only on the head and neck. Goltz syndrome results in skin irregularities across the entire body. Also, patients with MLS do not have the abnormal fatty tissue deposits seen under the skin of Goltz syndrome patients. Finally, MLS does not have the clefting of the hands or feet (syndactyly) or incomplete formation of certain structures of the eyes (coloboma) seen in Goltz syndrome.

Identification of the gene responsible for MLS makes genetic testing for this dominant trait potentially possible.

Treatment and management

The treatment and management of MLS is directed toward the symptoms seen in each patient. All those affected with MLS will need eye care, including surgeries, to potentially repair damaged areas of the cornea and sclera. Some individuals may require skin care treatments depending on the severity of the skin abnormalities.

In cases of patients with a diaphragmatic hernia, emergency surgery shortly after birth may be necessary to attempt to repair the damaged area. Unfortunately, most cases of this type of hernia cannot be surgically corrected, and the patient will die.

In cases of patients with a lack of the septum pellucidum in the brain, anti-seizure medication may be necessary to control the seizures.

Genetic testing is currently available for family members, particularly to detect carrier frequency for at-risk females while pregnant.

Prognosis

MLS is lethal in males prior to birth. In females, a full life expectancy is possible if the complications are not severe and if medical treatment is followed.

Most problems of the cornea and sclera of the eye associated with MLS can be treated with corrective lenses or potentially surgically repaired with corneal implants or laser surgery.

Seizures, if present, can generally be controlled by anti-seizure medications.

Developmental delays in growth, motor ability, speech, and intellect occur in some, but not all, cases of MLS. The amount of delay that is observed is directly related to the severity of seizure activity in the brain caused by the malformation, or lack, of the septum pellucidum.

Micro syndrome

Definition

Micro syndrome is a rare genetic disorder. Children born with this condition may experience intellectual disability, seizures, visual impairment, difficulty eating, weakness, numbness, and/or abnormal sensations in the limbs.

Alternate names associated with micro syndrome are Warburg micro syndrome, WARBM, and Warburg Sjo Fledelius syndrome.

Description

Researchers described and named micro syndrome in 1993, but others had reported patients with what was probably the same malady as early as 1949. In the 1993

Symptoms of Micro syndrome

Mental retardation
Seizures
A small head (microcephaly)
Slow development of the external reproductive organs
Abnormally small eyes
Visual impairment
Cloudiness of the eye lenses (cataracts)
Drooping eyelid (ptosis)
Difficulty swallowing and therefore feeding
An undersized jaw (micrognathia)
A beaked nose
Decreased muscle tone (hypotonia)
Weakness and numbness in the limbs
Abnormal sensations in the limbs
Inability of the limbs to fully extend (joint contracture)
Delayed puberty

(Gale)

description, the researchers noted the symptoms of a Pakistani brother and sister and their male cousin. The symptoms included a small head and eyes, cataracts and near blindness, intellectual disability, excessive facial hair, decreased muscle tone (hypotonia), and incontinence.

Micro syndrome is an inherited disorder resulting from mutations in a gene that carries instructions for a membrane-associated Rab3 protein. This protein is important in the secretion of various substances from cells. These substances include neurotransmitters (chemicals that transmit nerve impulses) and hormones. The mutated gene produces faulty proteins, which in turn inhibit the proper flow of neurotransmitters and/or hormones and can lead to a wide range of symptoms.

Genetic profile

Located on chromosome 2, the *RAB3GAP* gene carries the blueprint for making the Rab3 protein, which actually comes in two forms. This gene is important in several normal functions, which include the following:

- Transmission of signals between nerve cells and between other cells and nerve cells. This function allows nerve impulses to travel properly, so that the body may move and function correctly.
- Release of hormones from cells. Hormones travel in the bloodstream to other areas of the body, where they can have an effect on such body processes as growth and development, sexual function and reproduction, and metabolism.

Mutations in the *RAB3GAP* gene are believed to lead to defects in both the transmission of nerve impulses and the secretion of hormones from cells. A study from 2015

KEY TERMS

Agenesis/hypoplasia of the corpus callosum—Birth defect in which the two halves of the brain are not properly separated.

Cataracts—Cloudiness of the eye lenses.

Hypogenitalism—Retarded development of the external reproductive organs.

Hypotonia—Decreased muscle tone.

Joint contracture—Inability of the limbs to fully extend.

Microcephaly—Small head.

Micrognathia—Undersized jaw.

Neurotransmitters—Chemicals that transmit nerve impulses.

Paresthesia—Presence of abnormal sensations in the limbs.

Ptosis—Drooping eyelid.

- abnormally small eyes
- visual impairment
- cloudiness of the eye lenses (cataracts)
- drooping eyelid (ptosis)
- difficulty swallowing and therefore feeding
- undersized jaw (micrognathia)
- beaked nose
- decreased muscle tone (hypotonia)
- weakness and numbness in the limbs
- abnormal sensations in the limbs, such as burning or tingling (paresthesia)
- muscle spasms
- inability of the limbs to fully extend (joint contracture)
- delayed puberty

Diagnosis

Examination

Doctors may focus primarily on the eyes to make a preliminary diagnosis of micro syndrome. Individuals with the disorder have congenital cataracts, small eyes, and visual impairment. The diagnosis is made more solid when the infant also shows other symptoms such as severe intellectual disability and movement problems.

Tests

The doctor may order cell samples be examined for the mutated *RAB3GAP* gene.

Procedures

The doctor may order an MRI (magnetic resonance imaging) scan to check the patient for malformations of the brain. Patients with micro syndrome typically show agenesis/hypoplasia of the corpus callosum, in which the two halves of the brain are not properly separated. An MRI can detect this abnormality.

Treatment and management

No treatment exists for micro syndrome, but some help is available to ease some of the symptoms.

Traditional

A common treatment for cataracts is surgery to remove or dissolve the affected lens. Doctors often recommend physical therapy to help improve muscle tone, to promote full extension of the limbs, and to counter muscle spasms. They may also suggest occupational therapy and speech therapy.

provided evidence that micro syndrome can also be caused by *RAB18* deficiency or dysregulation.

Demographics

Micro syndrome is very rare, and only a few dozen cases have been reported in the literature since its initial description in 1993.

Signs and symptoms

Micro syndrome is an autosomal recessive disorder. It occurs when individuals inherit a mutated *RAB3GAP* gene from each parent. The parents may not have the condition themselves but may be carriers. Carriers are individuals who do not develop the disorder themselves but may pass the gene for the disorder onto their children. If both parents are carriers, each of their children has a 50% chance of being a carrier and a 25% chance of acquiring the disorder. If both parents have micro syndrome, all of their children will acquire the disorder.

Many symptoms of micro syndrome are present at birth, but others will become evident as time goes on. Symptoms may include the following:

- intellectual disability
- seizures
- small head (microcephaly)
- hypogenitalism (retarded development of the external reproductive organs)

QUESTIONS TO ASK YOUR DOCTOR

- My baby has just been diagnosed with micro syndrome. What type of care is available to help with my child's mental development, and how much improvement should I expect?
- I do not feel equipped to care for my child on my own. What resources are available in my area?
- My spouse and I are carriers and would like to have a child. Is prenatal testing available to determine whether a baby has micro syndrome? Is there a way, perhaps through preimplantation genetic diagnosis, to ensure that we have a baby that does not have the disorder?

Drugs

For recurring seizures, doctors may prescribe anti-seizure medication.

Prognosis

Individuals with micro syndrome are of normal weight at birth, but soon show signs of slowed growth. Other symptoms such as evidence of intellectual disability, decreased muscle tone, and movement impairment may also soon begin appearing. By the first birthday, the baby typically has experienced muscle spasms. Children with this disorder can speak few if any words by the time they are ten years old. Many experience incontinence, and some may be unable to walk or even sit up on their own. Puberty is delayed. Vision may decline over time.

Miller-Dieker syndrome

Definition

Miller-Dieker syndrome (MDS) is a rare genetic disorder. Its signs and symptoms include severe abnormalities in brain development as well as characteristic facial features. Additional birth defects may also be present.

Description

MDS was named for the two physicians, J. Miller and H. Dieker, who independently described the condition in the 1960s. The hallmark of MDS is lissencephaly (smooth brain), a condition in which the outer layer of the brain, the cerebral cortex, is abnormally thick and lacks the normal convolutions (gyri). In some areas of the brain, gyri are fewer in number but wider than normal (pachygyri). Other areas lack gyri entirely (agyri). Normally, during the third and fourth months of pregnancy, the brain cells in the baby multiply and move to the surface of the brain to form the cortex. Lissencephaly is caused by a failure of this nerve cell migration. MDS is often called Miller-Dieker lissencephaly syndrome.

Genetic profile

When MDS was first described, geneticists thought it followed an autosomal recessive pattern of inheritance. However, in the early 1990s, several patients with MDS

were found to be missing a small portion of the short arm of chromosome 17 (17p13.3). This is called a partial deletion of chromosome 17. MDS is now classified as a “micro-deletion syndrome” because it is the result of the absence of genes that are normally located in this region of chromosome 17. In 1993, research scientists identified one of the genes in this region. They named it *LIS1* for “first lissencephaly gene” because it appeared to be important in normal brain formation. The main evidence for this was that the *LIS1* gene was missing in a number of individuals with isolated lissencephaly; that is, lissencephaly without the additional characteristics found in MDS. In 2003, researchers identified 12 additional genes consistently deleted in patients with MDS. From these recently identified genes the *YWHAE* gene is believed to play a large role in the MDS phenotype and the *CRK* gene is thought to cause the symptom of growth restriction. Because the full breadth of this syndrome’s phenotype requires the deletion of multiple genes located near each other, MDS has also been described as a contiguous gene syndrome.

Most genes, including all genes on the autosomes (non-sex chromosomes), are normally present in pairs. Individuals with MDS who have a micro-deletion of a small region of the short arm of one copy of their chromosome 17 still have one normal copy of this chromosome region on their other chromosome 17. For this reason, MDS is said to be due to “haploinsufficiency,” the term for a genetic condition caused by the lack of function of only one of the two copies of a gene. As with other haploinsufficiency syndromes, MDS has also been described as having an autosomal dominant pattern of inheritance.

Individuals with MDS usually die in infancy. Because they do not live to the age where they can reproduce, they cannot transmit MDS to their offspring. Eighty percent of individuals with MDS have it as the result of a new (*de novo*) deletion of a small part of the short arm of one chromosome 17 in just the one egg or sperm that formed that individual. The parents of these affected individuals have normal chromosomes without deletions. This means that their risk of having another child with MDS is very low (probably less than 1%). The other 20% of those with MDS have the syndrome because one of their parents carries a rearrangement of one copy of their own chromosome 17. The rearrangement can be an inversion or a balanced translocation between chromosome 17 and one of the other chromosomes. Since the rearrangement is balanced, that is, all the chromosome material is present but in a rearranged form, the parent is normal. However, when that parent produces an egg or a sperm, the balanced chromosome rearrangement can go through a further rearrangement. This results in a portion of the short arm of chromosome

17 being deleted. The individual who develops from that egg or sperm will have MDS.

Demographics

MDS is present in fewer than 1 in 100,000 births. There is no information to suggest that the syndrome is more common in any particular ethnic or racial group.

Signs and symptoms

Infants with MDS are usually small at birth. Characteristic facial features may include a high forehead with furrows and vertical ridges; indentation of the temples; a small, upturned nose; up-slanting eyes; a small mouth; a thick, broad upper lip with a thin border; low-set ears; and occasionally, a cleft palate. Some infants with MDS also have birth defects involving the heart and kidneys. Signs and symptoms can vary among MDS patients. This may relate to the actual size or exact location of the chromosome 17 deletion in that individual.

MDS infants have a very limited capacity for development due to the lissencephaly and associated brain abnormalities. Intellectual disability is severe to profound. Infants with MDS may be able to do little more than roll over. Convulsions (seizures) develop within a few weeks of birth and can be severe. Most newborns with MDS have low muscle tone (hypotonia), but later develop stiffness (spasticity) and an arching of the body (opisthotonos). Poor feeding leads to a failure to thrive and increases the risk of pneumonia because the infants can accidentally inhale baby formula into their lungs. Head size is usually in the normal range at birth, but poor brain growth means that, by the age of one year, the children have a smaller-than-normal head size (microcephaly).

Diagnosis

MDS is not the only disorder associated with lissencephaly. Autosomal dominant, autosomal recessive, and X-linked patterns of inheritance have been described among the more than two dozen genetic syndromes featuring this brain abnormality. Less commonly, lissencephaly can be the result of fetal infections such as prenatal cytomegalovirus (CMV). An accurate diagnosis of MDS is important not only because it can provide a prognosis for the affected child, but because it can give parents an estimate of their risk for having another child with MDS.

MDS may be suspected in the newborn period if an infant has the characteristic facial features along with low muscle tone. Studies of the infant’s brain by CAT scan or MRI will show the smooth brain surface. After the diagnosis of MDS is made on the basis of these signs

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman’s abdomen into her uterus to draw out a small sample of the amniotic fluid from around the fetus. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Autosomal dominant—A pattern of genetic inheritance where only one abnormal gene is needed to display the trait or disease.

Autosomal recessive—A pattern of genetic inheritance where two abnormal genes are needed to display the trait or disease.

Cerebral cortex—The outer surface of the cerebrum made up of gray matter and involved in higher thought processes.

Chorionic villus biopsy—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted either through the mother’s vagina or abdominal wall and a sample of cells is collected from around the early fetus. These cells are then tested for chromosome abnormalities or other genetic diseases.

Contiguous gene syndrome—A genetic syndrome caused by the deletion of two or more genes located next to each other.

FISH (fluorescence in situ hybridization)—Technique used to detect small deletions or rearrangements in chromosomes by attempting to attach a fluorescent (glowing) piece of a chromosome to a sample of cells obtained from a patient.

Haploinsufficiency—The lack of one of the two normal copies of a gene. Haploinsufficiency can result in a genetic disorder if normal function requires both copies of the gene. Haploinsufficiency is one explanation for a dominant pattern of inheritance.

Hypotonia—Reduced or diminished muscle tone.

Inversion—A type of chromosomal defect in which a broken segment of a chromosome attaches to the same chromosome, but in reverse position.

Lissencephaly—A condition in which the brain has a smooth appearance because the normal convolutions (gyri) failed to develop.

Micro-deletion syndrome—A collection of signs and symptoms caused by a deletion of a gene or genes that is too small to be seen through the microscope.

Microcephaly—An abnormally small head.

Opisthotonos—An arched position of the body in which only the head and feet touch the floor or bed when the patient is lying on their back.

Translocation—The transfer of one part of a chromosome to another chromosome during cell division. A balanced translocation occurs when pieces from two different chromosomes exchange places without loss or gain of any chromosome material. An unbalanced translocation involves the unequal loss or gain of genetic information between two chromosomes.

X-linked—Located on the X chromosome, one of the sex chromosomes. X-linked genes follow a characteristic pattern of inheritance from one generation to the next.

and symptoms, it is very important to study the infant’s chromosomes to check for the characteristic chromosome 17 deletion. This is done by sending a small sample of the infant’s blood to a cytogenetics laboratory. Trained laboratory personnel (cytogeneticists) first examine the infant’s chromosomes through the microscope using traditional techniques. If no deletion or other chromosome rearrangement is detected in this step, newer methods can be used to search for deletions that are too small to see by ordinary means (micro-deletions). A special technique called FISH (fluorescent in situ hybridization) can detect chromosome regions where very small pieces of DNA are missing. This test is usually done on the same blood sample.

Carrier detection

When a chromosome deletion is found in an infant, both parents’ chromosomes should also be studied to determine if one of them carries a chromosome rearrangement such as a balanced translocation. Although most parents of infants with MDS have normal chromosomes, in approximately 20% of children, one parent will have a chromosome rearrangement, which can increase the risk for having another child with MDS. Other family members should also be offered chromosome studies because these balanced chromosome rearrangements can be passed down through a family undetected, and thus, other family members may be carriers. The first step in studying other family members is for a geneticist or

QUESTIONS TO ASK YOUR DOCTOR

- What genetic and/or chromosomal changes are responsible for Miller-Dieker syndrome?
- What are the most prominent physical and mental manifestations of this disorder?
- Can Miller-Dieker syndrome be diagnosed prenatally, and if so, how?
- What lifespan should we anticipate for a child born with this disorder?

genetic counselor to obtain a detailed family history and construct a pedigree (family tree) to determine which family members should be offered testing.

Prenatal diagnosis

If a couple has had one child with MDS, they can be offered prenatal diagnosis in future pregnancies. This option is particularly important for the 20% of MDS families where one parent carries a balanced chromosome rearrangement. The risk for these couples of having another affected child depends on the exact type of chromosome rearrangement present and may be as high as 25%–33%. For families in which both parents' chromosomes are normal, the risk of having another child with MDS is low (1% or less). Either chorionic villus sampling (CVS) or amniocentesis can be used early in a pregnancy to obtain a small sample of cells from the developing embryo for chromosome studies. Early prenatal diagnosis by ultrasound is not reliable because the brain is normally smooth until later in pregnancy. Couples who are considering prenatal diagnosis should discuss the risks and benefits of this type of testing with a geneticist or genetic counselor.

Treatment and management

There is no cure for MDS, and treatment is usually directed toward comfort measures. Because of the feeding problems and risk of pneumonia, surgeons often place a tube between the stomach and the outside of the abdomen (gastrostomy tube). Feedings can be made through the tube. Seizures are often difficult to control even with medication.

Prognosis

Death often occurs in the first three months of life, and most infants with MDS die by two years of age, although there have been reports of individuals living for several years.

Mitochondrial disease

Definition

Mitochondrial disease is a group of disorders in which organelles (structures) inside the cell, called mitochondria, do not function properly. Mitochondria produce most of the energy used by a cell and, in turn, by the body. When they malfunction, the cell dies. When enough cells die, the entire body is at risk for death. This lack of energy and cellular death cause the muscle weakness and other symptoms of mitochondrial disease.

Description

Mitochondria are organelles that play a crucial role in providing energy to a cell by creating a substance called adenosine triphosphate (ATP) that helps transfer

energy. Mitochondria have their own DNA consisting of 37 genes called mitochondrial DNA (mtDNA). Mitochondrial disease occurs when one or more of these 37 genes or others that support them mutate, causing the mitochondria to malfunction. Researchers have identified hundreds of different mitochondrial disorders with individual genetic causes.

Mitochondrial disease may be primary or secondary. Primary mitochondrial disease is caused by a mutation of any gene that produces protein used directly by mitochondria. Secondary disease is caused by mutations in a gene that does not directly produce protein or is not directly involved in energy production. These mutations may, however, eventually result in reduced energy production. Secondary mitochondrial disease is often seen in people with Alzheimer's and Parkinson's disease.

Some of the more common types of mitochondrial disease are the following:

- Alpers' progressive sclerosing poliodystrophy (Alpers' disease)
- Barth syndrome
- Chronic progressive external ophthalmoplegia (CPEO)
- Dominant optic atrophy
- Friedreich's ataxia
- Hereditary paraganglioma
- Hereditary spastic paraplegia
- Kearns-Sayre syndrome
- Leber optic neuropathy
- Leigh and Leigh-like syndrome
- Mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes (MELAS)
- Myoclonic epilepsy with ragged red fibers (MERRF)
- Neuropathy, ataxia, and retinitis pigmentosa (NARP)
- Pearson syndrome
- Wolfram syndrome

Genetic profile

Mitochondria contain 37 genes; however, that is not the full expression of genes that is necessary to make mitochondria or for them to function properly. According to geneticists, it takes more than 3,000 genes to produce a mitochondrion; of those, only 37 originate from mitochondria. The majority of the genes are created in the cell nucleus and transported, via proteins, to the mitochondria. Of the thousands of genes used to produce and maintain mitochondria, only 3%, or about 100 genes, are used to produce the ATP involved in energy production; the remaining 97% of the genetic material is used for other purposes. These genes are used in processes such as fetal development to help immature cells

differentiate into the cells needed to grow and mature. As a person ages, these genes become essential for building and maintaining cells. A cell cannot create RNA or DNA without mitochondria. Every organ in the body needs mitochondria to perform the functions necessary for life. The exact genetic mutations determine which form of mitochondrial disease is present and which organs are affected. These mutations may be either spontaneous or inherited and may involve mtDNA or nDNA. This variation and the large number of possible genes involved is why there are hundreds of different mitochondrial diseases and why, even among individuals with similar genetic mutations, there is such a diverse spectrum of symptoms. It is a common clinical finding that individuals with the same mtDNA mutation do not have the same disease.

Because of the vast number of possible mutations that can cause mitochondrial disease, diagnosis has been difficult. In the past, genetic testing was time consuming and costly and might not identify the correct mutation. With the development of next-generation sequencing (NGS), a genetic testing process that allows a person's entire genome to be sequenced in one day, it has become much easier to identify specific mutations and to identify the best treatment options. In January 2015, the Mitochondrial Medicine Society issued their next-generation sequencing statement in support of NGS as the preferred diagnostic method, stating, "NGS is the most appropriate test given the complexity of symptoms and the genetic heterogeneity of mitochondrial disease and is medically important for most patients in order to guide treatment."

NGS is also called high-throughput sequencing. There are several different genetic sequencing technologies that may be used when performing NGS, such as Illumina (Solexa) sequencing, ion torrent: proton/PGM sequencing, Roche 454 sequencing, or SOLiD sequencing. These new technologies and others in development are causing NGS to become more affordable and more important as a diagnostic tool for many diseases.

Demographics

The exact number of people with mitochondrial disease is not known. It is estimated that every year there are between 1,000 and 4,000 children born with mitochondrial disease in the United States. However, there is no way to know the exact number because of the wide spectrum of symptoms and many types of mitochondrial disease. Because of this, many people are misdiagnosed. According to the United Mitochondrial Disease Foundation, mitochondrial disease is approaching childhood cancer in numbers of children affected. It affects males and females and people of all races.

Signs and symptoms

Mitochondrial disease affects multiple organ systems in the body. The main symptoms include muscle weakness; neurological problems such as seizures and ataxia; vision and hearing impairment; cardiac, liver, or respiratory disease; developmental delay; poor growth; diabetes; and increased susceptibility to infection. The presence of three or more of these symptoms is an indicator for mitochondrial disease, especially if symptoms involve more than one organ system.

More specific symptoms affecting individual organ systems vary depending on which type of mitochondrial disease is present and which genes have been mutated. The following are symptoms of mitochondrial disease by body system.

Brain

- Atypical cerebral palsy
- Autistic features
- Dementia
- Developmental delays
- Intellectual impairment
- Migraines
- Neurological disturbances
- Psychiatric disorders
- Seizures
- Strokes

Eyes and ears

- Hearing loss and deafness
- Ophthalmoplegia
- Optic atrophy
- Ptosis
- Retinitis pigmentosa
- Strabismus
- Visual impairment and blindness

Heart, liver, and kidneys

- Heart block (cardiac conduction defects)
- Liver failure
- Renal tubular acidosis or wasting

Muscles

- Cramping
- Diarrhea or constipation
- Dysmotility
- Gastrointestinal problems such as reflux and IBS
- Hypotonia
- Muscle pain
- Weakness

KEY TERMS

Apoenzyme—An enzyme that cannot function without assistance from other molecules called cofactors.

ATP—Adenosine triphosphate. The molecule used by the cells of the body for energy.

Autosomal recessive disorder—A disorder where two copies of a dysfunctional gene must be inherited for the trait to present. The gene is present on the non-sex chromosomes.

Cofactor—A substance that is required by an enzyme to perform its function.

Ketosis—An abnormal build-up of compounds called ketones in the blood. This condition usually indicates a problem with blood sugar regulation.

Metabolic acidosis—High acidity (low pH) in the body due to abnormal metabolism, excessive acid intake, or retention in the kidneys.

Methylmalonic acid—An intermediate product formed when certain substances are metabolized.

Sudden infant death syndrome (SIDS)—The unexpected, sudden death of a child under one year of age. Often called “crib death.”

TCA cycle—Formerly known as the Krebs cycle, this is the process by which glucose and other compounds are broken down into forms that are directly useable as energy in the cells.

Nerves

- Absent reflexes
- Fainting
- Neuropathic pain
- Weakness—intermittent or constant

Pancreas and other glands

- Diabetes
- Exocrine pancreatic failure (inability to make digestive enzymes)
- Parathyroid failure (low calcium)

Systemic

- Fatigue
- Poor weight gain
- Respiratory problems
- Short stature

- Vomiting

Diagnosis

Because there are so many possible genetic causes for mitochondrial disease and such a wide variation of symptoms, there is no one reliable diagnostic test. If an individual has three or more of the main symptoms, then mitochondrial disease is suspected. It is important to find a physician who specializes in the diagnosis and treatment of mitochondrial disease. The first step of diagnosis is to collect a detailed medical and family history. Next, a physical and neurological examination will be performed. A muscle biopsy may be performed. During muscle biopsy a small piece of muscle is removed and examined for abnormal muscle structure, in particular “ragged red fibers,” which indicate a specific type of mitochondrial disease. Muscle biopsy as a diagnostic tool has several limiting factors. It is invasive and painful, and children usually require general anesthesia for it to be performed. There can be false positive results, and—particularly in patients with secondary mitochondrial disease—the results may be normal even in the presence of the disease.

There are multiple laboratory blood tests used in the process of diagnosing mitochondrial disease, such as blood enzyme tests; several types of lactate tests; glucose, ammonia, amino, and organic acid tests; BUN; and CBC.

Genetic testing, including NGS, has become the most accurate and preferred method for diagnosing mitochondrial disease. While NGS is the preferred method of the Mitochondrial Medicine Society, there are other genetic tests that may be used. However, they are limited to use when specific types of the disease are suspected because they test only a few genes at a time. Other genetic tests include Mitochondrial DNA Point Mutations and Mitochondrial DNA Southern Blot.

Other testing procedures may be performed to assess specific symptoms and specific organ systems, such as magnetic resonance imaging (MRI) of the brain, retinal exams, EKG and echocardiograms (ECHO), thyroid function test, and audiograms.

Treatment and management

Treatment for mitochondrial disease is generally used to improve quality of life, reduce symptoms, and slow the progression of the disease. There is no cure.

There are standard treatments for many symptoms, such as physical therapy for individuals with muscle weakness and physical limitations and anticonvulsants for those with seizures. Supplements such as riboflavin, coenzyme Q, and carnitine (a specialized amino acid) may be used to help increase energy level and stamina

QUESTIONS TO ASK YOUR DOCTOR

- What type of mitochondrial disease do I have (does my child have)?
- Is there a special diet I should follow?
- Should I take vitamins, and if so, which ones?
- Do I need more testing? If so, what type?
- If I have mitochondrial disease, will my children have it, too?

for those who are experiencing fatigue, and there are many medications available to treat other symptoms such as nausea, infection, and pain.

There are dietary recommendations for individuals with metabolic diseases such as mitochondrial disease. It is recommended to avoid fasting, eat at regular intervals during the day and night, monitor fat intake and eat more or less fat depending on the type of mitochondrial disease present, avoid access iron in the diet, and avoid toxins such as cigarette smoke and alcohol.

Prognosis

The prognosis for patients with mitochondrial disease varies greatly, depending on the type of disease. Some individuals will have mild symptoms, while others will continue to worsen. In the most serious cases, the disease will lead to death.

Mitochondrial replacement therapy (MRT)

Definition

Mitochondrial replacement therapy, also known as mitochondrial replacement technique (MRT) or mitochondrial donation, is the only approach known as of 2021 to prevent a mitochondrial disease in human offspring. Given the lack of treatments for these severe diseases and the limitations of prenatal diagnosis, researchers have focused on preventing the transmission of mitochondrial diseases through germline gene replacement therapy. MRT is used during in vitro fertilization (IVF) to replace mitochondria with harmful mutations within a female oocyte (a cell that develops into an ovum by meiosis). The healthy replacement mitochondria are obtained from a donated oocyte. Because children born as a result of MRT and IVF have genetic material derived from two women and one man, they have been referred to in the popular press as three-parent babies.

Description

Mitochondrial diseases

Some background information about mitochondrial diseases is necessary in order to understand both the significance of MRT and the controversies surrounding it. Mitochondrial diseases are a group of metabolic disorders in which defective mitochondria within the affected person's cells fail to produce enough energy to meet the body's needs. Mitochondria are microscopic organelles found within all cells of the human body except red blood cells. Sometimes called the powerhouses of the cell, mitochondria convert energy derived from food into adenosine triphosphate (ATP), an organic molecule necessary for most cell functions. But because mitochondria perform a wide range of functions within different body tissues and organs, the symptoms of mitochondrial diseases vary widely in location and severity, ranging from muscular weakness, loss of balance, nausea, vomiting, developmental delays and dementia, to pain, kidney or liver failure, vision loss, and difficulty breathing. Most mitochondrial

diseases appear in humans before 20 years of age; some affect infants and are often fatal.

The website of the United Mitochondrial Disease Foundation (UMDF) contains detailed descriptions of 43 different mitochondrial diseases, but researchers estimate that there are at least several hundred disorders in this category. The exact number of people affected by mitochondrial diseases is not known, because these disorders are often misdiagnosed. Most mitochondrial diseases are genetic disorders. They may be caused either by mutations in the nuclear DNA in the cell or by mutations in the mitochondrial DNA (abbreviated as mtDNA). Most mitochondrial function is encoded by the DNA in the cell nucleus, which in humans is inherited from both parents. In contrast, mtDNA is inherited only from the mother; it contains only 37 genes and encodes 13 proteins. Another difference is that while there are only two copies of DNA in a human cell nucleus, each mitochondrion contains between two and ten copies of mtDNA.

As there are about 500 mitochondria in an average human cell (although liver and muscle cells may contain thousands), the difference in the number of DNA copies means that mutations occur at a much higher rate in mtDNA than in nuclear DNA. When mitochondria multiply during the normal process of cell division, they can accumulate random mutations, a condition called heteroplasmy. In some people, only a few mitochondria are affected by these mutations. In others, however, the number of mutant mitochondria increases over time until the mutant organelles dominate the pool of mtDNA. When this threshold is reached, typically in adolescence or early adult life, the person will begin to show symptoms of a mitochondrial disease. About 0.5% of the population carries mtDNA mutations, and about one person in every 5,000 (0.02%) is at risk of developing a mitochondrial disease.

In vitro fertilization

MRT is a recent specialized form of in vitro fertilization, or IVF, which has helped couples with fertility difficulties have children since 1978. About eight million children around the world have been born through IVF as of 2021. The basic IVF technique involves the administration of hormone therapy to the intended mother to stimulate the release of multiple eggs into the uterus. The eggs are retrieved, selected for health and maturity, and either mixed with sperm or fertilized by the injection of a single sperm into an egg.

The resultant embryos are allowed to mature for a short period of time and then subjected to genetic testing to screen for genetic disorders, abnormal chromosomes, or defective mitochondrial DNA. The embryos that pass

screening are returned to the intended mother's uterus, where it is hoped that at least one will implant and produce a successful pregnancy.

Types of MRT

Four major types of MRT have been used since the 1990s, one of which is no longer used as of 2021.

Ooplasmic/cytoplasmic transfer

Ooplasmic/cytoplasmic transfer is the oldest form of MRT, which was introduced in the 1990s to assist older women who were having difficulty conceiving. In this form of transfer, ooplasm containing proteins, mRNA, mitochondria, and other organelles was taken from a donor's egg, combined with a single sperm from the patient's husband, and injected into the intended mother's egg. A baby girl was born in a New Jersey hospital in 1997 following this type of MRT; another 30 babies were born as a result of cytoplasmic transfer between 1997 and 2001, even though the FDA banned the procedure in 1998 after three of the earliest children born through the use of the technique were found to have developmental disorders (two cases of Turner's syndrome and one of autism spectrum disorder).

Maternal spindle transfer

Maternal spindle transfer (MST) has been used when the intended mother's eggs indicate the presence of mutant mtDNA. The term *spindle* in this context refers to a microscopic network of microtubules (sometimes called spindle fibers) that forms during cell division to pull chromosomes to the poles of the cell during the phase of cell division called metaphase. To perform MST, an oocyte is first removed from the intended mother. When it reaches the metaphase stage of cell division, the spindle-chromosome complex is removed from the intended mother's oocyte, which is then discarded. The spindle complex is then transferred to a donated oocyte that has had its nuclear DNA removed. The result is a mature egg that contains a selection of the mother's haploid DNA along with healthy mitochondria from the donor. The egg is then fertilized with the father's sperm.

After fertilization, the embryo is allowed to grow until it forms a blastocyst, which is an early pre-implantation stage of the embryo consisting of a hollow sphere of 16 to 40 cells. The blastocyst can then be investigated with pre-implantation genetic testing for the presence of mtDNA mutations. If no mutations are found, the blastocyst can be implanted in the intended mother's uterus.

The spindle transfer technique has been performed only rarely since its first use in 2014, as the number of births among women at risk of transmitting diseases

caused by defective mtDNA is estimated to be quite small—about 150 per year in the United Kingdom and 800 per year in the United States.

Pronuclear transfer

In pronuclear transfer (PNT), the oocyte from the mother and the oocyte from the donor are both fertilized with sperm from the same person. The male and female pronuclei (the nucleus of an ovum or sperm before these have united to form the definitive nucleus of an impregnated ovum) are removed from each fertilized egg prior to their fusing, and the pronuclei from the recipient's fertilized egg are inserted into the fertilized egg from the donor. As with MST, the fertilized egg is then allowed to form a blastocyst, which can be subjected to pre-implantation genetic testing before it is implanted in the mother's uterus.

Polar body transfer

In polar body transfer (PBT), a polar body, which is a small cell with very little cytoplasm created when an oocyte divides, is taken from the intended mother and used in its entirety instead of using material extracted from the normal egg. The advantage of PBT is that there is a greatly reduced chance of transmitting defective mitochondria from the intended mother, because polar bodies contain very few mitochondria.

Limitations, risks, and controversies

The most important limitation of MRT is that its long-term risks and benefits are unknown as of 2021, because so few children have been born as a result of its use. The parents of an American child born in Mexico in 2016 have refused to allow ongoing testing of the child's mtDNA. This refusal means that the success of the first use of the maternal spindle transfer technique cannot be fully evaluated. In the United Kingdom, 14 women were given permission to undergo MRT after it was legalized in 2015, but it is not known as of 2021 how many children have been born from these procedures, because of the parents' wishes for privacy.

MRT has a number of known risks, mostly related to the number of different laboratory procedures involved. It requires pre-implantation genetic screening of the mother; pre-implantation genetic diagnosis of the fertilized egg (which carries its own risk of disrupting the development of the embryo); and in vitro fertilization. In addition, all current MRT techniques involve physical disruption of oocytes, which may cause unexpected damage. Moreover, the need to perform precisely timed actions during the development and fertilization of the eggs may result in the eggs either maturing abnormally

KEY TERMS

Adenosine triphosphate (ATP)—An organic molecule found in all living organisms, involved in energy production for metabolic processes and RNA synthesis.

Cytoplasm—All of the material within a cell enclosed by the cell membrane, excluding the nucleus. The cytoplasm includes cytosol, organelles (including mitochondria), and various inclusions.

Diploid—Referring to a cell or nucleus that contains two copies of genetic material, or a complete set of chromosomes.

Gamete—A sex cell (sperm or ovum) containing the haploid number of chromosomes, and capable of fusing with a gamete of the opposite sex to form a zygote.

Genetic drift—Variations in gene frequency within a population due to chance rather than mutation or natural selection.

Genome—The total amount of genetic information within an organism's chromosomes, including its genes and DNA sequences.

Germline—The population of a complex organism's cells that pass on genetic information to offspring.

Germline cells include eggs, sperm, and fertilized eggs.

Haploid—Referring to cells that have only one chromosome of each type and therefore have only one complete set of genes.

Heteroplasmy—The presence of two or more sources of mitochondrial DNA within a cell, person, or mitochondrion. It is an important factor in determining the likelihood or severity of a mitochondrial disease.

In vitro fertilization (IVF)—A form of assisted reproduction technology in which a human ovum (egg) is combined with sperm outside the body in a laboratory container ("in vitro" means "in a glass").

Leigh syndrome—A rare genetic disease associated with mutations in either mitochondrial DNA or nuclear DNA, and characterized by degeneration of the central nervous system. It is named for Archibald Denis Leigh, a British psychiatrist who first described the syndrome in 1951.

Meiosis (pronounced my-OH-sis)—The process of cell division during the production of ova and sperm, in which the material in the chromosomes undergoes recombination (first-stage meiosis), and

or normal fertilization failing to occur. Last, some of the intended mother's mtDNA will be carried over into the donated egg. Studies of both animal and donated human embryos indicate that the carryover of pathogenic DNA is about 2%, which some researchers consider unlikely to cause disease in the offspring. On the other hand, a group of Japanese researchers reported in 2020 that some embryonic stem cell lines showed evidence of genetic drift, or the reversion of healthy donated mtDNA to pathogenic mtDNA.

MRT is the subject of a number of controversies as of 2021:

- Whether the techniques involved in MRT have been adequately tested from the standpoint of the safety of the resultant offspring. A team of Dutch and Belgian researchers argued in 2020 that scientific innovation has been generally been favored over safety concerns.
- Whether MRT is a form of germline gene therapy or heritable genetic modification; or whether it simply involves donated intact mitochondria that do not affect the DNA in the cell nucleus—which would constitute alteration of the offspring's genome.
- Whether having a child genetically related to oneself should take precedence over all other ways of becoming a parent. A British and a Portuguese researcher noted that PNT and MST have both tended to increase couples' focus on the importance of a genetic link to a desired child without considering the low likelihood of success with these technologies. They suggest fertility counseling that presents couples with a balanced discussion of other options.
- Whether MRT is ready for "prime time" as a form of assisted reproductive technology (ART) or whether its routine use in present circumstances would be premature. Most researchers think that the proposed benefits of MRT to infertile couples are more theoretical than actual as of 2021.
- Whether women who desire genetically related children should have the ultimate say about using MRT. Two American researchers maintain that women in the United States have a constitutional right to reproductive autonomy and that denying them the right to MRT amounts to a violation of "a parental right to genetic affinity."
- Whether MRT is a step down a "slippery slope" of unwarranted experimental procedures driven by

the chromosomes are reduced to a single set of 23 instead of the normal number of 23 pairs (second-stage meiosis).

Metaphase—A stage in the cycle of cell division in which the cell's genetic material condenses into chromosomes, which become visible and line up in the center of the dividing cell.

Mitochondria (singular, mitochondrion)—Organelles in the cytoplasm of cells that contain genetic material and enzymes responsible for converting food to usable energy.

Mitochondrial replacement therapy (MRT)—A technique to prevent or treat certain genetic diseases by replacing the mitochondria in one or more cells. It is also called mitochondrial donation.

Oocyte (pronounced OH-eh-site)—A diploid cell in females from which an egg or ovum develops by meiosis.

Organelle—A specialized structure found within a cell that performs a specific function or carries out a specific life process. Mitochondria are organelles.

Polar body—Either of two small cells produced during the two meiotic divisions in the production of

an oocyte. Polar bodies contain only small amounts of cytoplasm and eventually disintegrate.

Pronuclear transfer—A mitochondrial replacement technique in which the mother's egg is first fertilized by the father's sperm; then the two pronuclei are inserted into a donor egg that has been fertilized and has had its own nucleus removed.

Pronucleus (plural, pronuclei)—The nucleus of a sperm or egg cell during the process of fertilization.

Three-parent baby—A term used in the mass media to describe a baby produced from the genetic material of one man and two women through the use of mitochondrial replacement technologies and three-person in vitro fertilization (IVF). It is not a scientific term.

Turner syndrome—A chromosomal disorder with a 45,X or 45,X0 karyotype that affects only females, in which one of the X chromosomes is either partially or completely missing. Most women with Turner syndrome are infertile because of a lack of ovarian function.

Zygote—A fertilized egg cell that results from the union of two gametes, a female egg and a male sperm.

commercial interests rather than patients' needs. The assisted reproductive technology market in the United States is largely unconstrained by government agencies, insurance companies, or research universities, and it is undergoing consolidation into a few large chains of consumer-oriented ART centers. An American researcher noted that the now-abandoned cytoplasmic transfer method of MRT was encouraged by several commercial firms before the FDA banned the procedure.

Legal and regulatory status of MRT

Because MRT is controversial, its legal and regulatory status varies from country to country as of 2021. To date, the United Kingdom is the only country in which MRT is legally permissible.

United Kingdom

As of 2021, MRT is allowed in the United Kingdom, but is permitted only within clinics approved by the country's Human Fertilization and Embryology Authority (HFEA), and only for patients approved by the HFEA. To date, only women at high risk of transmitting a severe

mitochondrial disease to offspring and for whom pre-implantation genetic testing is not an alternative have been approved for MRT. These approved patients must sign an informed consent form stating that they understand that the risks and benefits of MRT are not yet well understood.

Canada

According to MitoCanada, MRT is illegal in Canada under the provisions of the *Assisted Human Reproduction Act* (AHRA) of 2004, "and research on these techniques is illegal even if the resulting embryo will never be implanted in a uterus." As of late 2019, Canadian health agencies had not formally reviewed the newer techniques of MRT.

United States

MRT has not been approved by the U.S. Food and Drug Authority (FDA) for use in the United States as of mid-2021. The agency states that its "jurisdiction includes human cells used in therapy involving the transfer of genetic material by means other than the union of gamete nuclei." In 2014, the FDA convened a meeting of an advisory committee "to discuss oocyte modification in

QUESTIONS TO ASK YOUR DOCTOR

- Do you think there should be limits to the types of assisted reproductive technology allowed?
- Should the FDA approve the use of MRT in the United States? If so, should it approve all forms of MRT in current use or only one?
- What do you consider the most significant risks of mitochondrial replacement therapy?
- Have you ever treated a patient at high risk of bearing a child with a mitochondrial disease? If so, what advice did you offer?

assisted reproduction for the prevention of mitochondrial disease or treatment of infertility.”

The meeting was followed in 2015 by a request from the FDA to the Institute of Medicine (IOM; now called the National Academy of Medicine or NAM) to produce a report on the social and ethical issues involved in mitochondrial replacement therapy. The IOM’s report concluded that MRT is ethically permissible provided that two conditions are met: 1) treatment should be limited to women at risk of transmitting a severe mitochondrial disease; and 2) research should be limited at least initially to male embryos, because female embryos produced by MRT would result in heritable genetic modifications. Paternal mtDNA is not transmitted to offspring, and thus changes made to mtDNA in the male germline are not heritable.

The FDA posted its most recent statement on MRT on March 16, 2018, to the effect that “Congress has included provisions in annual federal appropriations laws [since 2015] that prohibit FDA from accepting applications for clinical research using MRT. Therefore, clinical research using MRT in humans cannot legally proceed in the United States. The FDA maintains the authority to investigate and take enforcement action in the event that it becomes aware of noncompliance with the laws and regulations administered by FDA.”

Because of the FDA’s refusal to allow the use of MRT within the United States, the sole American child born as a result of MRT was delivered in a Mexican hospital in 2016. The baby boy’s mother has Leigh syndrome, a rare neurological disorder caused by a mutation in her mtDNA. The physician, John Zhang, runs the New Hope Fertility Center in New York City. Other American women who are interested in MRT to prevent mitochondrial disease in their offspring must travel to

foreign clinics as of 2021. Zhang is currently offering the maternal spindle transfer technique in such clinics at a cost of \$80,000 to \$100,000 per patient—which places the procedure beyond the reach of most patients.

Other countries

China banned MRT after a trial of the pronuclear transfer method resulted in the death of two fetuses. Singapore considered legalizing MRT in 2018 during a process that included consulting the general public as well as bioethicists and lawyers, but no legislation has been passed officially as of 2021. Countries in which children have been born following the use of MRT include Greece, the Ukraine, and Spain.

Clinical trials

There are no clinical trials of any form of mitochondrial replacement therapy registered with the NIH as of mid-2021.

Moebius syndrome

Definition

Moebius (möbius) syndrome is a condition in which the facial nerve is underdeveloped, causing paralysis or weakness of the muscles of the face. Other nerves to the facial structures may also be underdeveloped.

Description

Moebius syndrome has been called "life without a smile" because the paralysis of the facial muscles, the most constant feature, leads to the physical inability to form a smile even when happy feelings are experienced. The facial nerve is one of a group of 12 nerves known as the cranial nerves because they originate in the brain. The facial nerve is also known as the seventh cranial nerve. The sixth cranial nerve, also called the abducens, controls blinking and back-and-forth eye movement and is the second most commonly affected cranial nerve in Moebius syndrome. Additional cranial nerves affected in

some patients control other eye movements and other functions such as hearing, balance, speech, and feeding.

During pregnancy, certain exposures, such as to the drugs misoprostol or thalidomide, appear to increase the risk of Moebius syndrome. Moebius syndrome cannot be prevented since its cause is unknown. Pregnant women should avoid any kind of illegal drugs, especially cocaine or methamphetamines, as well as misoprostol or thalidomide.

Individuals with Moebius syndrome may also have abnormalities of their limbs, chest muscles, and tongue. The chance of intellectual disability appears to be increased in people with Moebius syndrome, but most people with the disorder have normal intelligence.

Genetic profile

Most cases of Moebius syndrome are isolated and do not appear to be genetic, but occurrence in multiple individuals within some families indicates that there are multiple genetic forms.

Chromosomes 13, 3, and 10 appear to contain genes causing forms of Moebius syndrome, now named, respectively, types 1, 2, and 3.

One family was reported in which two brothers and their male cousin, who were the sons of sisters, all had Moebius syndrome along with other physical abnormalities and intellectual disability. Boys only have one X chromosome and can inherit an X-linked disease from their unaffected mothers, who have two X chromosomes. The pattern of affected children in this family is typical of X-linked inheritance, so it is suggested that there may be a gene involved in Moebius syndrome on the X chromosome as well. If this is the case, the son of a woman with an altered Moebius gene on one X chromosome would have a 50% chance of inheriting the gene and having the condition. A man with this type of Moebius syndrome would be unlikely to have affected children since his daughters would likely have one normal X chromosome from their mother and his sons would receive his Y chromosome, not his X chromosome. In another family, a brother and sister with unaffected parents had Moebius syndrome, suggesting autosomal recessive inheritance, in which two altered copies of a gene are required to have the disorder. In an autosomal recessive disorder, a couple in which each parent carries one altered copy of the disease gene has a 25% chance of having a child with the condition with each pregnancy.

Demographics

Moebius syndrome is extremely rare and does not seem to affect any particular ethnic group more than

QUESTIONS TO ASK YOUR DOCTOR

- What are the treatment options for Moebius syndrome?
- Is surgery required?
- How will Moebius syndrome affect my child?

others. The families in which genes on chromosomes 3 and 10 were mapped were Dutch.

Signs and symptoms

The first sign of Moebius syndrome in newborns is an inability to suck, sometimes accompanied by excessive drooling and strabismus (crossed eyes). Also seen at birth in some patients are abnormalities of the limbs, tongue, and jaw. Children often have low muscle tone, particularly in the upper body. The lack of facial expression and inability to smile become apparent as children get older.

When cranial nerve palsy is associated with limb reduction abnormalities and the absence of the pectoralis muscles, the condition is known as Poland-Moebius or Möbius-Poland syndrome. Common limb abnormalities are missing or webbed fingers and clubfoot.

The prevalence of intellectual disability in Moebius syndrome is uncertain. It has been estimated in the past to be between 10% and 50%, but these numbers are thought to be overestimates resulting from the lack of facial expression and drooling seen in people with Moebius syndrome. In one study of familial cases of Moebius syndrome, 3% were reported to be intellectually disabled.

Diagnosis

Diagnosis of Moebius syndrome is made on the basis of clinical symptoms, especially the lack of facial expression. Since exact genes involved in Moebius syndrome had not yet been identified as of 2015, molecular genetic testing was not available at this time.

Treatment and management

The ability to smile has been restored in some cases of Moebius syndrome by surgery that transfers nerve and muscle from the thigh to the face. Other surgeries can be used to treat eye, limb, and jaw problems. In children with feeding problems, special bottles or feeding tubes are used. Physical and speech therapy are used when necessary to improve control over coordination, speech, and eating.

Prognosis

Moebius syndrome does not appear to affect lifespan, and individuals who are treated for their symptoms can lead normal lives.

Monosomy 1p36 syndrome

Definition

Monosomy 1p36 syndrome is a genetic disorder caused by the deletion of critical DNA on the chromosome pair 1. Children affected by this disorder have facial abnormalities, intellectual disability, and developmental delays. Monosomy refers to the deletion occurring on

only one of the chromosomes of the pair. The code 1p36 refers to the exact location on chromosome 1 where the deletion takes place. This location is at the terminal point of the chromosome. A syndrome is a collection of characteristics that tend to occur together in a disorder. Although it is a rare condition, monosomy 1p36 syndrome is the most common terminal deletion disorder.

Description

Monosomy 1p36 syndrome is a rare disorder. The severity of symptoms is diverse; however, most individuals experiencing this disorder have severe symptoms. The most notable symptoms are the facial features. Almost all children with this disorder have some level of intellectual disability. They also experience developmental delays. When they grow into adulthood, most require supportive living such as a group home with special services.

Risk factors

The cause of this disorder is the terminal deletion on chromosome 1, which is the largest human chromosome. Most cases of monosomy 1p36 syndrome appear to be from a spontaneous mutation. However, most spontaneous mutations take place on genes inherited from the mother. Evidence from research in 2009 suggested that the tendency for the deletion to occur is inherited as an autosomal dominant trait.

The facial characteristics of a person affected by monosomy 1p36 syndrome include deep-set eyes and flat nose bridge. Most individuals have a small head and ears that are disproportionate to one another. Another common characteristic is a pointed chin. Almost 65% of those affected are born with a cleft lip. Almost all children have low muscle tone leading to awkward motor skills.

Those affected with this disorder are born with some form of abnormality in the brain structure. In addition, most experience heart and hearing problems. Delays in language development and structural problems contribute to a lack of verbal communication.

There is no cure for the underlying condition, although genetic research is investigating ways to resolve similar conditions. Most treatment involves solving the individual symptoms and constant monitoring for further complications. Early intervention and life-long education is designed to help the affected person adapt to as independent a lifestyle as possible.

Genetic profile

The cause of this syndrome is a deletion of the continuous DNA on chromosome 1, which is responsible

for neurological functioning and normal development. The deletion is usually at the terminal point of the corrupted chromosome; however, in a few cases the deletion takes place in the middle of the strand. The rate of maternal chromosomes affected is slightly higher than paternal chromosomes affected with 60% of affected chromosomes coming from the mother's side. There are no notable differences in characteristics marking the differences in chromosomal differences.

Demographics

As of 2015, the estimate of this disorder's occurrence was between 1 in 5,000 and 1 in 10,000 newborns. Twice as many females are affected as males. No racial or ethnic ratios have been established.

Signs and symptoms

The most observable characteristics are the distinct facial features of an affected person. These include a prominent forehead and an underdeveloped midface. Included in the underdeveloped midface are the characteristics of a flat nose and flat nasal bridge. The eyes are deep set, and the openings are unusually small. Most people affected have microcephaly and brachycephaly. Microcephaly is a condition in which the circumference of the head is abnormally small for age and gender. Brachycephaly is a condition contributing to a flat head, in which the head is disproportionately wide but the front to back ratio is abnormally short. The ears are small, low set, and unaligned with each other. People with monosomy 1p36 syndrome have short stature in comparison to others of the same age and gender.

Developmental and intellectual disabilities are almost universal among those with this syndrome. Measures of intelligence are often below the standard for moderate intellectual disability; although some may be more severe. Language and speech development are often severely delayed. All measures of developmental milestones are later than observed in children from a normal population. Behavioral problems related to these delays are common with a greater than expected rate of self-injury.

The most serious and common congenital disorder is the heart malformation. This problem can be manifested as patent ductus arteriosus (failure of a prenatal bypass to close at birth) or cardiomyopathy (a congenital weakness of the heart muscle). Other serious congenital problems are associated with brain malformation. The related conditions include cerebral atrophy (loss of brain cells) and cerebral ventricular dilatation (condition where the amount of blood coming into the brain is greater than what can be accommodated by the blood vessels taking

blood away from the brain). Other congenital disorders include visual disability to some degree. Many individuals experience problems of the esophagus interfering with normal swallowing. Sensitivity in hearing is reduced to some degree in most affected people due to problems with the ear structure or to the nerve, but complete hearing loss is no greater than in the normal population.

Diagnosis

Many characteristics of monosomy 1p36 syndrome are observable from birth. Certainly the distinct facial characteristics can be identified as good evidence of the presence of monosomy 1p36 syndrome. There are no known cases of a diagnosis based on the observable features alone.

Examination

An examination of the newborn suspected of having this syndrome begins with noting the usual observable features, including a prominent forehead; a flat nose and nasal bridge; deep set eyes; abnormally small, flat head; and small, low set, unaligned ears. In addition to these easily observed features, most children with monosomy 1p36 syndrome have problems with the little finger on one or both hands. This fifth finger may be unusually short or pointed. Oftentimes the fifth finger is either curving toward the other fingers or is inflexible. In newborns, the anterior fontanelle (the soft spot of the head) is either unusually large or is unusually late in closing. Quite a few affected people experience seizures; therefore, it is appropriate to note in the clinical examination whether the child has had seizures.

Tests

Tests should be conducted for the expected congenital disorders, including problems of the heart and brain. Tests of reflexes and reaction can be conducted with a newborn to determine intellectual functioning. In early childhood, developmental tests can demonstrate the rate of developmental growth in comparison with normally developing children. However, a diagnosis of monosomy 1p36 syndrome cannot be definite without a test detecting the chromosome 1 deletion.

The main test for recognizing chromosomal disorders is fluorescence in-situ hybridization (FISH). This method of analyzing the structures of human genetics relies on fluorescent probes designed to link to specific genetic particles such as proteins, genes, or chromosomal material. If the correlating probe cannot link to the material for which it is designed, then the result is accepted as an absence of the material. In testing for monosomy 1p36 syndrome, the probes specific to a continuous pattern on

chromosome 1 would be injected into genetic material from the patient. If examination of the probes does not detect a continuous pattern, then it is confirmation that the person has monosomy 1p36 syndrome.

The condition can also be detected prenatally through amniocentesis.

Treatment and management

Treatment is focused on relieving discomfort caused by the secondary characteristics. Depending on what the characteristics are and how severe they are, there may be an effort to reverse the individual symptoms. However, there is little effort to find a cure for the underlying cause of the disorder.

One of the most important sources for treatment for the child diagnosed with monosomy 1p36 syndrome is early intervention for intellectual disability. Early intervention can assist the child in overcoming the challenges of developmental delay. As the child grows, the individual will require special services in school and rehabilitative services in adult life. Involving the child in early intervention can assist in making these later services more effective. The agency providing the early intervention can help educate and prepare the parents for the challenges that the child will face over the years. The best intervention is based in a day-care setting with the child living at home, unless the developmental disabilities are too severe. In that case, the child might be recommended to a residential facility.

The severity of any congenital physical problems has to be met appropriately from birth. Doing so requires constant observation and medical diagnosis. If the condition is not severe, it may not be dangerous to postpone treatment until later in life; however, diagnosis of the condition and its progress has to be constantly monitored over time.

Since most children with monosomy 1p36 syndrome have some level of a hearing disability, lessons in American Sign Language are often recommended. The children often have speech problems; therefore, learning sign language can improve their communication skills. Constant assessment of all symptomatic conditions, including language, intellectual functioning, heart condition, seizures, and hearing, is necessary throughout life.

There is no prevention for monosomy 1p36 syndrome. Genetic counseling and prenatal testing is available but is usually only conducted when one of the parents is suspected of being a carrier. Genetic counseling can help prospective parents recognize the risks of conceiving a child with this syndrome. If the risk is high, the parents might have the option of in vitro fertilization. With in vitro fertilization, the genetic diagnosis, done before implantation, can detect which available zygote has the least chance for the syndrome. The advantage of

QUESTIONS TO ASK YOUR DOCTOR

- What specific congenital disorders does my child have?
- How can we as parents monitor the many conditions of our child?
- What are the chances for my child to grow up to be independent?
- How can we determine what social services are available for our child at all stages of life?
- What can we as parents do to help our child better adapt?
- Where can we find out about trial treatments available now or in the future?

early detection through prenatal testing is that the necessary accommodations and interventions can be ready immediately after birth. The necessary tests for genetic counseling and prenatal assessment are not usually conducted unless there is a known family risk. Therefore, it is important to investigate one's family history. Furthermore, when there is a known risk, it is important to communicate that to all concerned.

Prognosis

There is no cure for monosomy 1p36 syndrome. The prognosis of this syndrome is related to the severity of the condition and the nature of the symptoms. There is a correlation between the extent of the deletion on chromosome 1 and the severity of the conditions of the syndrome. However, the deletion of chromosome 1p36 is never seen as a contributing factor in a fatality. The resulting congenital disorders are more often referred to as contributing to death of a person. Statistics on life expectancy are usually given in relation to those collected for the congenital disorders.

The prognosis for adapting to living conditions and for quality of life is related to the effectiveness and appropriateness of recommended treatments. Family members and advocates have to be constantly aware of the availability of necessary social services for those with developmental disabilities.

Mowat-Wilson syndrome

Definition

Mowat-Wilson syndrome is a rare genetic disorder characterized by moderate to severe mental impairment, distinctive physical features, and a collection of intestinal problems known as Hirschsprung's disease.

An alternate name associated with Mowat-Wilson syndrome is Hirschsprung Disease-Mental Retardation syndrome. A similar condition, called Goldberg-Shprintzen syndrome, is sometimes confused with Mowat-Wilson syndrome, but appears to have a different genetic basis.

Description

Mowat-Wilson syndrome is named for clinical geneticists David Mowat and Meredith J. Wilson, who, along with their research team, described the disorder in a 1998 issue of the *Journal of Medical Genetics*. In the article, they provided details about six children, five from New South Wales, Australia, and one from Manchester, England. The children were unrelated. Four of the six children had the following combination of primary symptoms:

- distinctive facial appearance, including large, uplifted earlobes
- intellectual disability

KEY TERMS

Agenesis/hypoplasia of the corpus callosum—Birth defect in which the two halves of the brain are not properly separated.

Cataracts—Cloudiness of the eye lenses.

Hypogenitalism—Retarded development of the external reproductive organs.

Hypotonia—Decreased muscle tone.

Joint contracture—Inability of the limbs to fully extend.

Microcephaly—Small head.

Micrognathia—Undersized jaw.

Neurotransmitters—Chemicals that transmit nerve impulses.

Paresthesia—Presence of abnormal sensations in the limbs.

Ptosis—Drooping eyelid.

- small head
- short stature
- severe constipation, intestinal blockage, and enlargement of the colon, a collection of symptoms known as Hirschsprung's disease, which first appeared when these patients were newborns

The remaining two patients had similar symptoms, but one did not develop Hirschsprung's disease until the age of three, and the other did not have Hirschsprung's disease but did experience chronic constipation. The researchers also noted that all six patients had "a generally happy, smiling affect," often with an open-mouthed expression.

Mowat and Wilson suggested that the cause of the disorder was a genetic mutation or the loss of a miniscule bit of a chromosome (known as a microdeletion). The researchers continued to collect evidence and review other patients with the same suite of symptoms and, in 2003, published their findings that the disorder, by then named Mowat-Wilson syndrome, resulted from the mutation of a specific gene, and this mutation need only affect one of the two copies of the gene in a cell to have an effect.

Genetic profile

The *ZEB2* gene is located on the long arm of chromosome 2. It carries the blueprint for the *ZEB2* protein, which is a transcription factor. Transcription factors

attach to DNA and regulate the expression of genes. In other words, they control whether certain genes' instructions are read. The *ZEB2* protein regulates those genes that have roles in early growth and development. In particular, the *ZEB2* protein is vital to the development of embryonic tissue called the neural crest, which later transforms into more specific tissues that are critical to a well-functioning nervous system, heart, and other systems and organs. This protein is also crucial in the development of a properly formed face and skull.

Individuals who have the mutated *ZEB2* gene cannot make enough properly functioning *ZEB2* protein, which causes the neural crest to suffer, and associated organs and tissues do not develop as they should.

Scientists know of more than 180 different mutations in the *ZEB2* gene that can lead to Mowat-Wilson syndrome. Usually, the mutation either completely deletes one copy of the gene or affects its instructions such that it makes shortened and nonfunctional *ZEB2* protein.

Demographics

Mowat-Wilson syndrome is a rare genetic disorder that affects individuals worldwide and appears to have no preference for gender, ethnicity, or geographic area. Information about its prevalence was not available as of 2015. There have been more than 200 reported cases of Mowat-Wilson syndrome globally.

Signs and symptoms

Mowat-Wilson syndrome results from a mutation in a gene that carries the instructions for making the protein called zinc finger E-box binding homeobox 2 (*ZEB2*). When a mutation of this gene, which is generally called the *ZEB2* gene, occurs, individuals cannot make a sufficient amount of the functioning *ZEB2* protein, and in some cases, they cannot make any at all. This protein is involved in the prenatal development of the nervous, gastrointestinal, cardiovascular, and other systems and tissues in the body. When it is lacking, a wide range of symptoms can arise.

Although this disorder has a genetic component, patients typically do not have a family history of it. Instead, Mowat-Wilson syndrome usually arises spontaneously, which means that it is not passed from one generation to the next, nor is it more likely in brothers or sisters of an affected individual. Mowat-Wilson syndrome is considered an autosomal dominant disorder, because individuals only need to have one copy of the mutated gene to develop the disorder.

Symptoms

Individuals with Mowat-Wilson syndrome have a wide range of symptoms, including characteristic facial features, some of which may be evident at birth, and moderate to severe mental impairment. Symptoms may include the following:

- small head (microcephaly)
- heavy eyebrows
- mental impairments that may be severe
- impaired, late-developing speech, or absent speech
- motor-skill delays, including late development of walking
- severe constipation, intestinal blockage, and enlargement of the colon (collectively known as Hirschsprung's disease)
- chronic constipation, even in the absence of Hirschsprung's disease
- short stature
- heart defects
- urinary tract/genital defects, such as the abnormally placed opening of the urethra or undescended testicles among males
- seizures
- improper separation of the two halves of the brain (agenesis/hypoplasia of the corpus callosum)

Facial features common to infants include:

- widely spaced, deep-set, large eyes
- square-shaped face
- broad nasal bridge, and an overall flat, or so-called saddle nose or boxer's nose with a rounded tip
- open, frequently smiling mouth
- full lower lip
- narrow, strongly pointed chin
- cup-shaped ears with large earlobes and a dimple in the middle of each lobe
- thick and horizontal (rather than arched) eyebrows

As the child ages, the facial features typically change in the following ways:

- chin becomes stronger
- rounded tip of the nose becomes more evident
- upper lip becomes narrow at the center point and outer edges, but full elsewhere
- continued smiling, open-mouthed expression
- blue-eyed children with black patches in their irises

Facial features continue to develop into adulthood, and patients generally have a long face with protruding jaw (prognathism); a long, pointed chin; very thick,

QUESTIONS TO ASK YOUR DOCTOR

- What can I do to help my child learn to walk?
- What specialists are available to help my child begin talking?
- Do seizure medications have any side effects?
- Should we consider prenatal genetic testing to make sure our next child does not have this disorder as well?

horizontal eyebrows; and a long nose that dips down toward the top of the upper lip.

Diagnosis

Examination

Notable facial features (which become more prominent as the affected individual ages), developmental delays, and intellectual disabilities aid in a preliminary diagnosis of Mowat-Wilson syndrome.

Tests

Genetic testing is used to detect *ZEB2* gene mutations that are indicative of the disorder.

Treatment and management

No cure is available. Individuals with this disorder are typically treated by a range of specialists that focus on various symptoms.

There is no way to prevent Mowat-Wilson syndrome. It is a genetic disorder that usually results from a mutation that occurs spontaneously.

Traditional

Depending on the severity of symptoms, the doctor may refer a patient to an orthodontist, ophthalmologist, urologist, cardiologist, or other specialist for additional symptom diagnosis and treatment. For instance, individuals may undergo an electroencephalogram (EEG) or magnetic resonance imaging (MRI) to check for the potential of neurologic problems, such as seizures.

Drugs

A doctor may prescribe anti-epileptic drugs to treat seizures. Additional medication may be of help in treating specific symptoms.

Prognosis

Initial symptoms, including characteristic facial features, are often seen soon after birth, and mental abilities become evident shortly thereafter. Toddlers generally have poor muscle tone and begin walking late (at about four years of age) or never develop this ability. Seizures may develop in infancy or in later childhood, but in about 10% of patients, seizures do not develop. Nearly one-half of patients develop congenital heart disease, and about 60% develop Hirschsprung's disease. Those without Hirschsprung's disease usually have chronic constipation.

Leslie A. Mertz, PhD

Moyamoya

Definition

Moyamoya is a progressive syndrome characterized by narrowing of the blood vessels in the brain. Moyamoya is the Japanese term for "cloud of smoke drifting in the air."

Description

The term "moyamoya" is used to describe how the arteries in the brain look in this syndrome, which was first described in the 1950s. There is no clear cause for this

disease. It can be caused genetically but can also occur as a result of other diseases. Moyamoya is seen in patients with a variety of diseases, including neurofibromatosis, trisomy 21 (Down syndrome), sickle cell disease, chronic meningitis, and as a side effect of irradiation.

Moyamoya is a disease of the blood vessels in the brain. The carotid arteries are two of the large arteries that allow blood to flow into the brain. The external carotid artery allows blood to reach areas within the neck, while the internal carotid artery travels to the brain and branches off into smaller vessels to reach all areas of the brain. In patients with moyamoya, there is a symmetric thinning of the width of the internal carotid arteries. The brain responds to this thinning by making the smaller blood vessels bigger, trying to get blood to the areas of the brain that are not getting enough. When dye is injected into the arteries of the brain (a cerebral angiogram), a characteristic pattern is seen. On the angiogram, this looks like a cloud of smoke.

Genetic profile

The primary form of moyamoya is seen most often in Japan. Studies have found the familial form to account for 7%–10% of the cases. A recent study focused on 16 families in order to find the genetic marker for the disease. The gene locus was found to be present on the short arm of chromosome 3, specifically 3p26–p24.2. Other studies have found possible involvement of genes on chromosomes 6 and 17 as well.

Demographics

Although the disease seems to occur most often in Japanese people, patients have been found throughout the world. It is thought that one in a million people are affected each year. The age of onset of the disease has two peaks, the first being in children under 10 years old, and the second in adults in their 20s–40s. Fifty percent of moyamoya cases are found in patients younger than ten years of age. Females seem to have moyamoya more often than males. The female-to-male ratio is 3:2.

Signs and symptoms

The first signs and symptoms of moyamoya tend to be different in children and adults. Children most often present with a sudden seizure or a stroke. Strokes can cause weakness on one side of the body. These are often brought on with exercise or fast breathing. Less severe strokes, called transient ischemic attacks (TIAs), can occur very often. During these TIAs, the weakness in the body is temporary and will not last more than a few hours. Over a period of years, strokes and TIAs leave patients with permanent weakness on both sides of the body, seizure disorders, and intellectual disabilities.

KEY TERMS

Angiography—Injecting dye into blood vessels so they can be seen on a radiograph or picture.

Chromosome—A microscopic thread-like structure found within each cell of the body that consists of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Stroke—A sudden neurological condition related to a block of blood flow in part of the brain, which can lead to a variety of problems, including paralysis, difficulty speaking, difficulty understanding others, or problems with balance.

While children will present with seizures or strokes, adults tend to present with intracerebral hemorrhage (bleeding within the brain). Depending on where the bleeding or strokes occur, there can be a variety of chronic symptoms, including speech disturbance, visual disturbance, headaches, difficulties with sensation, and involuntary movements (moving parts of the body when you do not intend to).

Diagnosis

Cerebral angiography is the main method of diagnosis. This is the best way to see the arteries in the brain and to assess their level of occlusion (blockage). Other methods of imaging have been used in an attempt to diagnose moyamoya. High-resolution imaging such as computed tomography scans (CT scans) do not show findings specific to this syndrome. However, areas of old strokes or bleeding can be seen. Magnetic resonance imaging (MRI) is also very sensitive at looking for old areas of stroke but cannot show which blood vessels may be blocked as compared with angiography. These non-invasive imaging techniques may, however, provide clues for the diagnosis. The doctor would then recommend angiography to confirm the diagnosis.

Treatment and management

There is no one best treatment for moyamoya. Medical therapy consists of drugs that prevent blood clot formation, such as aspirin. Drugs that help dilate the narrowed blood vessels, such as calcium channel blockers, are also used. Calcium channel blockers that have been successful include nicardipine and verapamil. These calcium channel blockers may also help with the

headaches that some patients may get during the course of their illness.

Many different surgical approaches have been used to help improve blood flow in these patients. It is not known what the long-term outcomes of these procedures are. The most popular operations are: encephaloduroarteriosynangiosis (EDAS), encephalomyosynangiosis (EMS), and superficial temporal artery-middle cerebral artery (STA-MCA) anastomosis.

In EDAS, an artery that sits under the scalp called the superficial temporal artery is separated from the skin. A small opening in the skull is then made. The artery from the scalp is then sewn into the surface of the brain. The piece of skull that was removed is then put back in place to protect the new connection. This procedure has also been termed pial syngiosis.

In the EMS procedure, a muscle overlying the temple region of the forehead, called the temporalis muscle, is detached. Once again, an opening in the skull is made and the muscle is placed on the surface of the brain.

In the STA-MCA operation, the scalp artery is connected directly to an artery in the brain. All of these surgical procedures attempt to provide blood to areas of the brain that are not getting enough. Although symptoms may be improved soon after surgery, it usually takes months for the new blood vessels to form.

Prognosis

The long-term risks due to complications in people with moyamoya disease are unknown. A study published in 2000 looked at 334 patients with moyamoya disease diagnosed between 1976 and 1994. Approximately 60% of the adults who had moyamoya had a cerebral hemorrhage at some point. Approximately 60% of the children who had moyamoya had a stroke or TIA at some point. Cerebral hemorrhage was found to be the most important factor that predicted a poor outcome. The overall effect of medical and surgical treatment on long-term outcomes was unknown as of 2015.

mRNA vaccine technology

Messenger ribonucleic acid (mRNA) is one of a variety of nucleic acids found in cells. It has a chemical composition similar to, but distinguishable from, DNA. Like DNA, it is capable of carrying the genetic code that translates to the amino acid sequence of proteins. Unlike DNA, mRNA works in the cytoplasm, or body of the cell separate from the chromosomes in the nucleus. In the cytoplasm, ribosomes read the genetic code of mRNA, and the ribosomes add amino acids to the growing protein according to the genetic code.

mRNA vaccine technology uses mRNA custom-made to direct the production of a protein. When a protein from a virus is desired, a custom-made mRNA molecule is delivered to the cytoplasm of cells with instructions for production of the desired viral protein. No live or attenuated virus is needed.

History of mRNA in Medical Research

mRNA has been in use for decades in experimental cancer treatments. Experimental Zika virus, rabies virus, and influenza virus vaccines have been developed and tested in animals. Notably, for influenza, the goal of an mRNA vaccine is to develop immunity with a vaccine that is easily manufactured and can be administered in one or two injections and does not require annual flu shots. Research focus shifted rapidly to SARS-CoV-2 early in the pandemic that began in 2019.

Emergence of SARS-CoV-2

SARS CoV-2 is a respiratory disease-causing virus newly introduced into the human population. The coronaviruses are a large viral family found throughout nature. They infect animals, including humans. Many common colds are caused by coronaviruses. A far more serious respiratory infection, COVID-19, caused by SARS-CoV-2, was

Illustration of an mRNA Ebola vaccine that uses replicon mRNA (messenger ribonucleic acid), a self-replicating nucleic acid, to prime a recipient's immune system. mRNA (yellow) that encodes ebola virus glycoprotein is extracted from an Ebola virus (left) and packaged in a dendrimer nanoparticle (blue). The dendrimer protects the mRNA from degradation when injected into the host and helps with delivery to a host cell. Once inside the host cell the mRNA produces Ebola virus glycoproteins, but not the virus itself. This foreign antigen activates the body's immune system (red cells) to produce antibodies that protect against future infections with the actual virus (far right). (Mikkel Juul Jensen/Science Source)

responsible for an outbreak near Wuhan China late in 2019 that spread globally.

Vaccination for disease prevention

Prevention of viral disease through vaccination requires that a sample of the virus be made available to the body to teach the immune system how to destroy the virus before infection is established and symptoms develop. COVID-19 mRNA vaccines deliver their genetic code to the interior of cells so that the cellular machinery can be used to make new viral proteins. Whether infected by the virus naturally or immunized, the spike protein becomes exposed on the outer surface of human cells. The immune system gets an example of the composition of the virus and mounts a response that prevents infection from closely related coronavirus.

The immune response is twofold: there are cellular and antibody components. The response destroys free viral particles after binding their spike protein with antibody. Infected cells are destroyed by white blood cells to stop them from producing virus particles. Then, through a cascade of events, cells able to produce mass

quantities of protective antibodies and white blood cells that can destroy infected human cells develop. Immunological memory resides in those antibody-producing and other white blood cells. A rapid and protective response is launched upon re-exposure to the virus or vaccine-derived spike protein, and infection is diminished in severity or prevented completely.

The vaccine mRNA must contain the genetic sequence of protein from the virus. Several research teams chose spike protein for vaccine research because it is accessible on the surfaces of infected cells and on free virus particles. The immune system has easy access to spike so that antibodies and cells can act on it. In addition to coding for the spike protein, the vaccine mRNA must contain code serving as instructions for the cell to correctly use the mRNA to make the protein.

Delivery of the vaccine to the interior of the cell

The gene gun is a device that works through the skin to "shoot" vaccine into cells. It has been used for mRNA delivery and vaccination in mice. Lipid or polymer-based

nanoparticles can be used to carry the mRNA and “melt” into the cell surface, delivering the mRNA to the cells’ interior. Vector-delivered mRNA is inserted into an unrelated virus that is unable to infect or cause disease. The virus vector enters cells and delivers the mRNA so that the spike protein can be made. Nanoparticle or vector delivery is used in the three COVID-19 vaccines used under an emergency use authorization in 2021.

COVID-19 Vaccine Safety

mRNA is a non-infectious platform. There is no risk of infection or mutations to human genes. Additionally, mRNA is degraded by normal cellular processes at a rate that can be controlled, so foreign substances do not remain in cells. The COVID-19 mRNA vaccines have high potency, ease of rapid development, and the potential for low-cost manufacture and safe administration.

Effectiveness of COVID-19 Vaccinations

All COVID-19 vaccines currently available in the United States have been shown to be safe and effective at preventing COVID-19. Between 85% and 95% of fully vaccinated people develop protective immunity to the virus. Vaccination is also likely to reduce the spread of virus to other people and limit its opportunities to reproduce and mutate into variants that vaccines are less effective at preventing. The duration of protective immunity is at least a few months, but remains to be seen.

Side effects of vaccination

Coronavirus vaccination may cause pain, redness, and swelling of the arm where the shot is given. Other typical and mild side effects are fatigue, headache, muscle pain, chills, fever, or nausea. Side effects after the second shot may be more intense than the ones experienced after the first shot. These side effects are normal signs that the body is building protection, and they should go away within a few days. Rarely reported side effects include allergic reactions. All people who get a COVID-19 vaccine should be monitored on site for 15 minutes for any developing side effects. Fewer than one in 1,000,000 patients develop serious blood clots weeks to months after vaccination. The rarity of serious side effects and the lethal nature of COVID-19 make the risk of vaccination worthwhile for most people.

Advantages of mRNA Vaccine Technology

These vaccines do not require the use of easily contaminated tissue culture or infectious virus. The process does not produce spike protein in a lab that must then be characterized or preserved before vaccination, because the spike protein is made in the cells of the person

receiving the vaccine. mRNA vaccines are potent, the technology has the capacity for rapid development, as with COVID-19 vaccines, and they have potential for low-cost manufacturing and safe administration.

Challenges of mRNA technology

COVID-19 vaccine production was easily scaled up under federal and international regulations meant to ensure purity, consistency, safety, and potency. Since viruses mutate while in circulation, an extensive system for monitoring infectious strains globally for newly emerging variants must alert public health authorities if the new variants require vaccine reformulation to mimic the variants.

Mucopolipidosis

Definition

Mucopolipidosis (ML) is a group of rare, inherited disorders that are characterized by the accumulation of complex fats, called mucolipids, in the cells of the body. The symptoms range from skeletal abnormalities and vision problems to physical retardation and intellectual disability.

Description

Types of mucopolipidosis

There are three major types of mucopolipidosis. Mucopolipidosis II (ML II, ML2), or ML disorder type II, is known as I-cell disease (ICD). Sometimes it is called Leroy disease, after Jules Leroy, who described the disorder in 1969. ML II is also known as N-acetylglucosamine-1-phosphotransferase (GNPTA) deficiency. GNPTA is the enzyme that is defective in ML II.

Mucopolipidosis III (ML III, ML3), or ML disorder III, is a milder form of ML II. In ML III, the enzyme GNPTA has reduced activity, whereas it has no activity in ML II. ML III was first described in 1966. It is often called pseudo-Hurler polydystrophy because its symptoms resemble a mild form of the mucopolysaccharide disorder known as Hurler syndrome. It is a polydystrophy because several systems of the body are affected.

In the past, ML II and ML III were classified as mucopolysaccharidoses (MPS II and MPS III, respectively). MPS is a condition in which complex sugars called mucopolysaccharides accumulate in the cells of the body. Although this may occur in ML, excess amounts of mucopolysaccharides are not excreted in the urine, as they are in MPS.

Mucopolipidosis IV (ML IV, ML4) was first described in 1974. It also is called ML disorder IV, Berman syndrome, or sialolipidosis. Recently the gene *TRMPL1*, a widely expressed cation channel protein expressed in lysosomes and late endosomes, has been implicated in ML IV.

Neuraminidase deficiency originally was classified as mucopolipidosis I (ML I). However, neuraminidase deficiency does not involve the accumulation of mucolipids.

Lipids

Lipids are large, complex biomolecules that are very important components of cell membranes. They also are used to store energy and are present in mucus secretions. Lipids are continually broken down and replaced. This breakdown of lipids occurs in a membrane-bound compartment or organelle within cells, called the

lysosome. The lysosome contains many enzymes that break down the lipids. These enzymes are produced outside of the lysosome and have to be transported into the organelle. The enzyme GNPTA attaches a signal to these enzymes that directs them to the lysosome.

Lysosomal storage diseases

MLs are classified as lysosomal storage diseases because the lysosomes accumulate lipids that cannot be broken down. Eventually, the lysosomes become so filled with lipids that the cells form structures called inclusion bodies to contain the lipids. Inclusion bodies give the cells a characteristic appearance. The name “I-cell disease” refers to these inclusion bodies.

Individuals with ML II or ML III have little or no GNPTA enzyme activity. Thus, the lysosomal enzymes cannot reach the lysosome to help break down lipids. ML II and ML III are caused by mutations, or changes, in one of the genes that encodes a part of GNPTA. A disorder called mucopolipidosis III, variant form, or complementation group C, is caused by a mutation in a gene that encodes a different part of GNPTA. The symptoms of this form of ML III are very similar to those of the more common type of ML III.

ML IV is caused by a mutation in the gene encoding a protein called mucolipin-1. In ML IV, membrane lipids and mucopolysaccharides accumulate in the lysosomes of cells throughout the body. Apparently, in the absence of mucolipin-1, these substances are transported to the lysosome rather than recycled to the cell membrane.

Genetic profile

All of the MLs are inherited as autosomal recessive traits. They are autosomal because the genes that are responsible for these disorders are located on autosomal chromosomes, rather than on the X or Y sex chromosomes. The traits are recessive because they are only expressed in individuals who have inherited two copies of the gene that causes the disorder, one copy from each parent.

Individuals with only one copy of a gene that causes ML are called carriers. They usually do not have symptoms of ML. The offspring of two carriers of an ML gene have a 25% chance of inheriting both genes and developing ML.

Demographics

MLs are very rare disorders that often have been misdiagnosed. Thus, the frequency of ML is not clear. Since MLs are recessive disorders that only develop when both parents are carriers of one of the ML genes, the condition most often occurs in the offspring of closely related

individuals, such as first cousins. These disorders are much more prevalent in small, isolated populations. For example, among French-Canadians in one region of Quebec province, it is estimated that 1 out of every 39 people carries a gene for ML II and 1 out of 6,184 infants has the disorder. In contrast, over a ten-year-period, only 35 infants with ML II or ML III were born in Great Britain. In the Republic of Ireland the carrier rate is 1 in 512, and in Northern Ireland the frequency is 1 in 15. In Portugal the frequency of ML II is 1 in 123,500 births, in Japan the incidence is 1 in 252,500 births, and in the Netherlands it is 1 in 625,000 births. The global carrier prevalence has been estimated to be between 1 in 158 and 1 in 316.

Although ML IV can occur in any nationality or ethnic group, more than 80% of all known cases are Jews of Eastern European descent (Ashkenazim). It is estimated that 1 out of 50 individuals of Ashkenazi descent is a carrier of ML IV. Worldwide, there are about 100 known cases of the disorder. However, it is thought that there are many more undiagnosed or misdiagnosed cases.

Signs and symptoms

The symptoms and the age of onset of ML II vary greatly, even within families. Some signs of ML II can be congenital, or present at birth. These may include the following:

- multiple abnormalities in bone formation, particularly in the hip
- limited mobility of the joints
- multiple abnormalities of the skull and face
- a fold of skin extending from the inner corner of the eyelid, called an epicanthal fold

ML II and ML III are progressive conditions. Infants may show few symptoms of the disorder until lipids begin to accumulate and damage cells. Additional symptoms of ML II may include the following:

- dwarfism
- delayed mental and physical development
- hearing loss
- heart disease in the aortic valve
- swollen liver and spleen

The symptoms of ML III are similar to those of ML II, but they are usually less severe. Additional signs of ML III may include the following:

- acne
- clouding of the cornea, the clear portion of the eye through which light passes
- enlarged tongue

KEY TERMS

Autosomal recessive—A pattern of genetic inheritance in which two abnormal genes are needed to display the trait or disease.

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes.

Carrier—An individual who possesses an unexpressed abnormal gene of a recessive genetic disorder.

Epicanthal fold—A wrinkle in the skin extending from the nose up to the eyebrow; it is sometimes associated with genetic anomalies.

Hydrolase—An enzyme that uses water to break down substances.

Inclusion body—An abnormal storage compartment inside a cell.

Lipid—Large, complex biomolecule, such as a fatty acid, that will not dissolve in water. A major constituent of membranes.

Lysosome—A membrane-enclosed compartment in cells, containing many hydrolytic enzymes; where large molecules and cellular components are broken down.

Mucolipid—A lipid that accumulates in cells in mucopolipidosis disorders.

Mucolipin-1—A protein in the cell membrane, probably a calcium ion channel, involved in recycling membrane lipids and deficient in mucopolipidosis IV.

Mucopolysaccharide—A complex molecule made of smaller sugar molecules strung together to form a chain. Found in mucous secretions and intercellular spaces.

N-acetylglucosamine-1-phosphotransferase (GNPTA)—Enzyme that attaches a signal to other enzymes and directs those enzymes to the lysosome; deficient in mucopolipidoses II and III.

ML IV is characterized by intellectual disability, physical retardation, and eye disorders. Many individuals with ML IV do not develop beyond the skill level of a one-year-old. However, some individuals with ML IV have very mild symptoms.

Infants with ML IV appear normal at birth. However, signs of the disorder usually become apparent during the first year. Often, clouding or opacity of the cornea is the first symptom, and vision problems may develop before

the age of one. The physical retardation and intellectual disability may be mild at first, but they often become severe as the disorder slowly progresses. Most individuals with ML IV never walk. Other signs of ML IV may include the following:

- delayed growth
- poor muscle tone
- crossed eyes
- puffy eyelids
- aversion to light
- degeneration of the retina, eventually leading to blindness

Diagnosis

In ML I, there is a high level of urinary glycosaminoglycans (GAGs), which is normal in ML II, allowing for a differential diagnosis between ML I and ML II.

ML II and ML III may be diagnosed by high levels of lysosomal enzymes, called hydrolases, in the blood. The following hydrolases are found to be 5- to 20-fold higher in plasma, leading to a differential diagnosis: β -D-hexosaminidase, β -D-glucuronidase, β -D-galactosidase, and α -L-fucosidase.

The absence of mucopolysaccharides in the urine indicates that the disorder is not a mucopolysaccharidosis. However, the urinary excretion of oligosaccharides is high.

The microscopic examination of various cells reveals inclusion bodies.

X-rays are used to detect skeletal abnormalities.

The initial diagnosis of ML IV usually results from a biopsy. A small piece from the skin or from the membrane underneath the eyelid is removed and examined under a microscope for the accumulation of lipids and mucopolysaccharides in storage bodies.

Treatment and management

There is no cure for ML. Management of symptoms, close medical monitoring, and supportive care are the primary treatments.

Surgery can remove the thin layer of cells that causes the corneal cloudiness that is characteristic of ML IV. However, the layer of cells will grow back. Physical, occupational, and speech therapy can improve the functioning of children with ML IV.

Prognosis

The life expectancy for individuals with ML is not known, although many do not survive childhood.

Mucopolysaccharidoses

Definition

Mucopolysaccharidoses (MPS) is a general term for a number of inherited diseases that are caused by the accumulation of mucopolysaccharides, resulting in problems with an individual's development. With each condition, mucopolysaccharides accumulate in the cells and tissues of the body because of a deficiency of a specific enzyme. The specific enzyme that is deficient or absent is what distinguishes one type of MPS from another. Before these enzymes were identified, the MPS disorders were diagnosed by the signs and symptoms that an individual expressed. The discovery of these enzymes resulted in a reclassification of some of the MPS disorders. These conditions are often referred to as MPS I, MPS II, MPS III, MPS IV, MPS VI, MPS VII, and MPS IX. These conditions are also referred to by their original names, which are Hurler, Hurler-Scheie, Scheie (all MPS I), Hunter (MPS II), Sanfilippo (MPS III), Morquio (MPS IV), Maroteaux-Lamy (MPS VI), Sly (MPS VII), and Hyaluronidase deficiency (MPS IX).

Description

Mucopolysaccharides are long chains of sugar molecules that are essential for building the bones, cartilage, skin, tendons, and other tissues in the body. Normally, the human body continuously breaks down and builds mucopolysaccharides. Another name for mucopolysaccharides is glycosaminoglycans (GAGs). There are many different types of GAGs, and specific GAGs are unable to be broken down in each of the MPS conditions. There are several enzymes involved in breaking down each GAG, and a deficiency or absence of any of the essential enzymes can cause the GAG to not be broken down completely and results in its accumulation in the tissues and organs in the body. In some MPS conditions, in addition to the GAG being stored in the body, some of the incompletely broken down GAGs can leave the body via the urine. When too much GAG is stored, organs and tissues can be damaged or function improperly.

Genetic profile

Except for MPS II, the MPS conditions are inherited in an autosomal recessive manner. MPS conditions occur when both of an individual's genes that produce the specific enzyme contain a mutation causing them to not work properly. When both genes do not work properly, either none or a reduced amount of the enzyme is produced. An individual with an autosomal recessive condition inherits one nonworking gene from each parent. These parents are called carriers of the condition. When two people are known carriers for an autosomal recessive condition, they have a 25% chance with each pregnancy to have a child affected with the disease. Some individuals with MPS do have children of their own. Children of parents who have an autosomal recessive condition are all carriers of that condition. These children are not at risk to develop the condition unless the other parent is a carrier or affected with the same autosomal recessive condition.

Unlike the other MPS conditions, MPS II is inherited in an X-linked recessive manner. This means that the gene causing the condition is located on the X chromosome, one of the two sex chromosomes. Since a male has only one X chromosome, he will have the disease if the X chromosome—inherited from his mother—carries the defective gene. Females will be carriers of the condition if only one of their two X chromosomes has the gene that causes the condition.

Demographics

The National Institute for Neurological Disorders and Stroke (NINDS) estimates that 1 in every 25,000 babies born in the United States has some form of

mucopolysaccharidosis. Males and females are affected equally.

Signs and symptoms

Each type of MPS is caused by a deficiency of one of the enzymes involved in breaking down GAGs. It is the accumulation of the GAGs in the tissues and organs in the body that causes the wide array of symptoms characteristic of the MPS conditions. The accumulating material is stored in cellular structures called lysosomes, and these disorders are also known as lysosomal storage diseases.

MPS I

MPS I is caused by a deficiency of the enzyme alpha-L-iduronidase. Three conditions, Hurler, Hurler-Scheie, and Scheie syndromes, are all caused by a deficiency of this enzyme. Initially, these three conditions were believed to be separate because each was associated with different physical symptoms and prognoses. Once the underlying cause of these conditions was identified, it was realized that these three conditions were all variants of the same disorder. The gene involved with MPS I is alpha-L-iduronidase (*IDUA*), which is located on chromosome 4p16.3.

MPS I H (HURLER SYNDROME). It has been estimated that approximately 1 in 100,000 will be born with Hurler syndrome. Individuals with Hurler syndrome tend to have the most severe form of MPS I. Symptoms of Hurler syndrome are often evident within the first year or two after birth. These infants often begin to develop as expected, but then reach a point where they begin to lose the skills that they have learned. Many of these infants may initially grow faster than expected, but their growth slows and typically stops by age three. Facial features also begin to appear "coarse." They develop a short nose, flatter face, thicker skin, and a protruding tongue. Additionally, their heads become larger and they develop more hair on their bodies with the hair becoming coarser. Their bones are also affected, with these children usually developing joint contractures (stiff joints), kyphosis (a "hunchback" curve of the spine), and broad hands with short fingers. Many of these children experience breathing difficulties, and respiratory infections are common. Other common problems include heart valve dysfunction, thickening of the heart muscle (cardiomyopathy), enlarged spleen and liver, clouding of the cornea, hearing loss, and carpal tunnel syndrome. These children typically do not live past age 12.

MPS I H/S (HURLER-SCHIE SYNDROME). Hurler-Scheie syndrome is felt to be the intermediate form of MPS I, meaning that the symptoms are not as severe as those in individuals who have MPS I H but not as mild

as those in MPS I S. Approximately 1 in 115,000 will be born with Hurler-Scheie syndrome. These individuals tend to be shorter than expected, and they can have normal intelligence; however, some individuals with MPS I H/S will experience learning difficulties. These individuals may develop some of the same physical features as those with Hurler syndrome, but usually they are not as severe. The prognosis for children with MPS I H/S is variable with some individuals dying during childhood, while others live to adulthood.

MPS I S (SCHEIE SYNDROME). Scheie syndrome is considered the mildest form of MPS I. It is estimated that approximately 1 in 500,000 will be born with Scheie syndrome. Individuals with MPS I S usually have normal intelligence, but there have been some reports of individuals with MPS I S developing psychiatric problems. Common physical problems include corneal clouding, heart abnormalities, and orthopedic difficulties involving their hands and back. Individuals with MPS I S do not develop the facial features seen with MPS I H, and usually these individuals have a normal lifespan.

MPS II (Hunter syndrome)

Hunter syndrome is caused by a deficiency of the enzyme iduronate-2-sulphatase. Individuals with Hunter syndrome are primarily male, because the gene that encodes iduronate-2-sulphatase (IDS) is located on the X chromosome, specifically at location Xq28. However, there have been rare reported cases of females being diagnosed with MPS II. Like many MPS conditions, Hunter syndrome is divided into two groups, mild and severe. It has been estimated that approximately 1 in 110,000 males are born with Hunter syndrome, with the severe form being three times more common than the mild form. The severe form is felt to be associated with progressive intellectual disability and physical disability, with most individuals dying before age 15. In the milder form, most of these individuals live to adulthood and have normal intelligence or only mild mental impairments. Males with the mild form of Hunter syndrome develop physical differences similar to males with the severe form, but not as quickly. Men with mild Hunter syndrome can have a normal lifespan and some have had children. Most males with Hunter syndrome develop joint stiffness, chronic diarrhea, enlarged liver and spleen, heart valve problems, hearing loss, and kyphosis, and tend to be shorter than expected. These symptoms tend to progress at different rates depending on if an individual has a mild or severe form of MPS II.

MPS III (Sanfilippo syndrome)

MPS III, like the other MPS conditions, was initially diagnosed by the individual having certain physical

characteristics. It was later discovered that the physical symptoms associated with Sanfilippo syndrome could be caused by a deficiency in one of four enzymes. Each type of MPS III is now subdivided into four groups, labeled A–D, based on the specific enzyme that is deficient. All four of these enzymes are involved in breaking down the same GAG: heparan sulfate. Heparan sulfate is mainly found in the central nervous system and accumulates in the brain when it cannot be broken down because one of those four enzymes is deficient or missing. The overall incidence of all four types of MPS III is estimated to be 1 in 70,000 births.

MPS III is a variable condition with symptoms beginning to appear between two and six years of age. Because of the accumulation of heparan sulfate in the central nervous system, the central nervous system is severely affected. In MPS III, signs that the central nervous system is degenerating usually are evident in most individuals between ages six and ten. Many children with MPS III develop seizures, sleeplessness, thicker skin, joint contractures, enlarged tongues, cardiomyopathy, behavior problems, and intellectual disability. The life expectancy in MPS III is variable. On average, individuals with MPS III live until they are teenagers, with some living longer and others not surviving as long.

MPS IIIA (SANFILIPPO SYNDROME TYPE A). MPS IIIA is caused by a deficiency of the enzyme heparan N-sulfatase. Type IIIA is felt to be the most severe of the four types, in which symptoms appear and death occurs at an earlier age. A study in British Columbia estimated that 1 in 324,617 live births are born with MPS IIIA. MPS IIIA is the most common of the four types in Northwestern Europe. The gene that causes MPS IIIA is N-sulfoglucosamine sulfohydrolase (*SGSH*), located on the long arm of chromosome 17 (location 17q25.3).

MPS IIIB (SANFILIPPO SYNDROME TYPE B). MPS IIIB is due to a deficiency in N-acetyl-alpha-D-glucosaminidase (NAG). This type of MPS III is not felt to be as severe as Type IIIA and the characteristics vary. Type IIIB is the most common of the four in Southeastern Europe. The gene associated with MPS IIIB is N-acetylglucosaminidase, alpha (*NAGLU*), also located on the long arm of chromosome 17 (location 17q21).

MPS IIIC (SANFILIPPO SYNDROME TYPE C). A deficiency in the enzyme heparan-alpha-glucosaminidase N-acetyltransferase (HGSNAT) causes MPS IIIC. This is considered a rare form of MPS III. The gene involved in MPS IIIC is located on chromosome 8 (location 8p11.1).

MPS IIID (SANFILIPPO SYNDROME TYPE D). MPS IIID is caused by a deficiency in the enzyme N-acetylglucosamine-6-sulfatase. This form of MPS III

is also rare. The gene involved in MPS IIID is glucosamine (N-acetyl)-6-sulfatase (*GNS*) located on the long arm of chromosome 12 (location 12q14).

MPS IV (Morquio syndrome)

As with several of the MPS disorders, Morquio syndrome was diagnosed by the presence of particular signs and symptoms. However, it is now known that the deficiency of two different enzymes can cause the characteristics of MPS IV. These two types of MPS IV are called MPS IV A and MPS IV B. MPS IV is also variable in its severity. The intelligence of individuals with MPS IV is often completely normal. In individuals with a severe form, skeletal abnormalities can be extreme and include dwarfism, kyphosis (outward-curved spine), prominent breastbone, flat feet, and knock-knees. Usually, one of the earliest symptoms seen in this condition is a difference in the way a child walks. In individuals with a mild form of MPS IV, limb stiffness and joint pain are the primary symptoms. MPS IV is one of the rarest MPS disorders, with approximately 1 in 300,000 born with this condition.

MPS IV A (MORQUIO SYNDROME TYPE A). MPS IV A is the “classic” or the severe form of the condition and is caused by a deficiency in the enzyme galactosamine-6-sulphatase. The gene involved with MPS IV A is galactosamine (N-acetyl)-6-sulfatase (*GALNS*) located on the long arm of chromosome 16 (location 16q24.3).

MPS IV B (MORQUIO SYNDROME TYPE B). MPS IV B is considered the milder form of the condition. The enzyme, beta-galactosidase, is deficient in MPS IV B. The location of the gene encoding galactosidase, beta 1 (*GLB1*) is located on the short arm of chromosome 3 (location 3p21.33).

MPS VI (Maroteaux-Lamy syndrome)

MPS VI, which is another rare form of MPS, is caused by a deficiency of the enzyme N-acetylglucosamine-4-sulphatase. This condition is also variable; individuals may have a mild or severe form of the condition. Typically, the nervous system and intelligence of an individual with MPS VI are not affected. Individuals with a more severe form of MPS VI can have airway obstruction, develop hydrocephalus (extra fluid accumulating in the brain), and have bone changes. Additionally, individuals with a severe form of MPS VI are more likely to die while in their teens. With a milder form of the condition, individuals tend to be shorter than expected for their age, develop corneal clouding, and live longer. It is estimated that 1 in 215,000 births is affected with MPS VI. The gene involved in MPS VI is arylsulfatase B (*ARSB*) located on the long arm of chromosome 5 (location 5q14.1).

KEY TERMS

Cardiomyopathy—A thickening of the heart muscle.

Enzyme—A protein that catalyzes a biochemical reaction or change without changing its own structure or function.

Enzyme replacement therapy—Medical treatment replacing an enzyme in patients in whom that particular enzyme is deficient or absent.

Joint contractures—Stiffness of the joints that prevents full extension.

Kyphosis—An abnormal outward curvature of the spine, with a hump at the upper back.

Lysosome—Membrane-enclosed compartment in cells, containing many hydrolytic enzymes; where large molecules and cellular components are broken down.

Mucopolysaccharide—A complex molecule made of smaller sugar molecules strung together to form a chain. Found in mucous secretions and intercellular spaces.

Recessive gene—A type of gene that is not expressed as a trait unless inherited by both parents.

X-linked gene—A gene carried on the X chromosome, one of the two sex chromosomes.

MPS VII (Sly syndrome)

MPS VII is an extremely rare form of MPS, occurring only 1 in 250,000 births, and is caused by a deficiency of the enzyme beta-glucuronidase. It is also highly variable, but symptoms are generally similar to those seen in individuals with Hurler syndrome. The gene that causes MPS VII is designated glucuronidase, beta (*GUSB*), located on the long arm of chromosome 7 (location 7q21.11).

MPS IX (Hyaluronidase deficiency)

MPS IX is a condition that was first described in 1996 and has been grouped with the other MPS conditions by some researchers. MPS IX is caused by the deficiency of the enzyme hyaluronidase. In the few individuals described with this condition, the symptoms are variable, but some develop soft-tissue masses (growths under the skin). Also, these individuals are shorter than expected for their age. The gene involved in MPS IX is encoded by hyaluronoglucosaminidase 1 (*HYAL1*) located on the short arm of chromosome 3 (possibly 3p21.31).

Diagnosis

While a diagnosis for each type of MPS can be made on the basis of the physical signs described, several of the conditions have similar features. Therefore, enzyme analysis is used to determine the specific MPS disorder. Enzyme analysis usually cannot accurately determine if an individual is a carrier for an MPS condition. This is because the enzyme levels in individuals who are not carriers can be similar to enzyme levels seen in individuals who are carriers for MPS. In many of the MPS conditions, several potential symptom-causing mutations have been found in each associated gene. If the specific mutation is known in a family, DNA analysis may be possible.

Once a couple has had a child with an MPS condition, prenatal diagnosis is available to them to help determine if a fetus is affected with the same MPS as their other child. This can be accomplished through testing fluid samples using procedures such as an amniocentesis or chorionic villus sampling (CVS). Each of these procedures has its own risks, benefits, and limitations.

Treatment and management

There is no cure for mucopolysaccharidosis; however, several types of experimental therapies are being investigated. Typically, treatment involves trying to relieve some of the symptoms. Early diagnosis and treatment have been associated with the most favorable outcomes. Targeted drug therapies are available for specific MPS groups. The FDA has approved the drug treatments for MPS I (Aldurazyme, 2003), MPS II (Elaprase, 2006), MPS IVA (Vimizim, 2014), and MPS VI (Naglazyme, 2005). For multiple forms of MPS, the current gold standard of therapy is haematopoietic stem cell transplant, particularly if diagnosed before 2.5 years of age. For MPS I, II, and VI, enzyme replacement therapy is available. Enzyme replacement therapy has proven useful in reducing non-neurological symptoms and pain.

Many individuals with an MPS condition have problems with airway constriction. This constriction may be so serious as to create significant difficulties in administering general anesthesia. Therefore, it is recommended that surgical procedures be performed under local anesthesia whenever possible.

No specific preventive measures are available for genetic diseases of this type. For some of the MPS diseases, biochemical tests are available that will identify healthy individuals who are carriers of the defective gene, allowing them to make informed reproductive decisions. There is also the availability of prenatal diagnosis for all MPS disease to detect affected fetuses.

QUESTIONS TO ASK YOUR DOCTOR

- What are the most serious medical problems that arise because of mucopolysaccharidosis?
- What kinds of treatments or medications are available for the control of mucopolysaccharidosis?
- Are there clinical trials recruiting patients for the MPS that my child has been diagnosed with?
- Is it necessary to have periodic medical check-ups to monitor the progress of MPS in my child?

Clinical trials

Clinical trials on mucopolysaccharidoses are sponsored by the National Institutes of Health (NIH) and other agencies. As of 2015, NIH was reporting 115 ongoing and completed studies.

Examples include:

- The evaluation of the use of enzyme replacement therapy in mucopolysaccharidosis II (MPS II). (NCT00069641)
- A study evaluating the combined treatment using both enzyme replacement therapy and haematopoietic stem cell transplant (the current gold standard therapy) in patients with mucopolysaccharidosis I (MPS I). (NCT00176891)
- The development of a registry to provide information to better characterize the natural history and progression of MPS I as well as the clinical responses of patients receiving enzyme replacement therapy. (NCT00144794)

Clinical trial information is constantly updated by NIH, and the most recent information on mucopolysaccharidoses trials can be found at: <http://clinicaltrials.gov>.

Prognosis

Individuals affected with MPS are affected by many similar clinical features with different degrees of severity. While most undergo a time of normal development, this is followed by a decline in both physical and mental function. The specific syndrome affects the prognosis. For example, children affected with Hurler syndrome often do not live beyond age ten, while a child diagnosed with Scheie syndrome may live to adulthood, and an individual diagnosed with Hunter syndrome, which is a more mild type of MPS, may live into his or her 50s or beyond.

Muir-Torre syndrome

Definition

A syndrome is a condition in which a certain set of features is regularly seen. In Muir-Torre syndrome, the consistent features are skin tumors (sebaceous neoplasms) and internal organ cancers, most commonly colon cancer.

Description

Muir-Torre syndrome is named for two doctors who provided some of the earliest descriptions of the condition, E. G. Muir in 1967 and D. Torre in 1968. Originally thought to be separate conditions, it is now known that Muir-Torre syndrome is a phenotypic subtype of Lynch syndrome (also known as hereditary non-polyposis colon cancer [HNPCC]) and that disease occurs due to

Additional screening recommendations for females with Muir-Torrie syndrome

Test/Procedure	Age	Frequency
Breast exam	20 40	Every 3 years Annually
Pelvic exam	181 or sexually active	Annually
Pap smear	181 or sexually active	Annually
Mammogram	40 50	Every 1–2 years Annually
Endometrial biopsy	Menopause	Every 3–5 years after onset

(Gale)

alterations in the same genes. Some of the features of the conditions are the same, including increased risk of colorectal cancer (cancer of the colon and rectum) and cancer of other organs. Both conditions are hereditary cancer predisposition syndromes, meaning that the risk of cancer has been linked to an inherited tendency for the disease. A unique feature of Muir-Torre syndrome is the skin tumors. The most common skin tumors associated with Muir-Torre syndrome are benign (non-cancerous) or malignant (cancerous) tumors of the oil-secreting (sebaceous) glands of the skin. Another relatively common skin finding is the presence of growths called keratoacanthomas.

Genetic profile

HNPCC and Muir-Torre syndrome are allelic, meaning that they are due to changes in the same genes. Genes, the units of instruction for the body, can have changes or mutations that develop over time. Certain DNA sequence errors are repaired by the protein products of a class of

Screening recommendations for patients with Muir-Torrie syndrome

Test/Procedure	Age	Frequency
Physical exam	20+ 40+	Every 3 years Annually
Digital rectal exam	Any	Annually
Gualac of stool for occult blood	Any	Annually
Lab work-up	Any	Annually
Carcinoembryonic antigen		
Complete blood cell count with differential and platelet count		
Erythrocyte sedimentation rate		
Serum chemistries (SMA-20)		
Urinalysis		
Chest roentgenogram	Any	Every 3–5 years
Colonoscopy	Any If positive for polyps	Every 5 years Every 3 years

(Gale)

genes known as mismatch repair genes. When mutations in these genes occur, the resulting proteins are unable to function properly, and there is a higher chance of cancer due to the alterations that accumulate in the genetic material. Heritable mutations in at least five mismatch repair genes have been linked to HNPCC, although the majority, over 90%, are in the *MLH1* and *MSH2* genes. Mutations in *MLH1* and *MSH2* also have been reported in Muir-Torre syndrome, although most have been *MSH2* mutations. The location of the *MLH1* gene is on chromosome 3 at 3p21.3, while the location of *MSH2* is chromosome 2, 2p21. Genetic testing for *MLH1* and *MSH2* is available, but the detection rate for mismatch repair gene mutations is less than 100%. Therefore, diagnosis of Muir-Torre syndrome is based not only on genetic testing alone but also on the presence of the typical features of the disease.

Muir-Torre syndrome is inherited in an autosomal dominant fashion. Thus, both men and women can have Muir-Torre syndrome, and only one gene needs to be altered to have the syndrome. Children of individuals with Muir-Torre syndrome have a 50% chance of inheriting the gene alteration. The symptoms of the syndrome are variable, and not all individuals with the condition will develop all of the features.

Demographics

At least 250 cases of Muir-Torre syndrome have been reported. It is estimated that between 1 in 200 to 1 in 2,000 people in Western countries carry an alteration in the genes associated with HNPCC, but the rate of Muir-Torre syndrome itself has not been clarified. More males than females appear to exhibit the features of Muir-Torre syndrome. The average age at time of diagnosis of the syndrome is around 55 years.

Signs and symptoms

Skin findings

Sebaceous neoplasms typically appear as yellowish bumps on the skin of the head or neck but can be found on the trunk and other areas. The classification of the different types of sebaceous neoplasms can be difficult, so microscopic evaluation is usually required for the final diagnosis. Keratoacanthomas are skin-colored or reddish, firm skin nodules that are distinct from sebaceous neoplasms upon microscopic examination. The skin findings in Muir-Torre syndrome can either appear before, during, or after the development of the internal cancer.

Internal findings

Internal organ cancers are common in Muir-Torre syndrome. Several individuals with Muir-Torre syndrome

KEY TERMS

Allelic—Related to the same gene.

Benign—A non-cancerous tumor that does not spread and is not life-threatening.

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes.

Colectomy—Surgical removal of the colon.

Colonoscopy—Procedure for viewing the large intestine (colon) by inserting an illuminated tube into the rectum and guiding it up the large intestine.

Colorectal—Of the colon and/or rectum.

Gene—A building block of inheritance that contains the instructions for the production of a particular protein, and is made up of a molecular sequence found on a section of DNA. Each gene is found at a precise location on a chromosome.

Genitourinary—Related to the reproductive and urinary systems of the body.

Hereditary non-polyposis colon cancer (HNPCC)—A genetic syndrome causing increased cancer risks, most notably colon cancer. Also called Lynch syndrome.

Keratoacanthoma—A firm nodule on the skin typically found in areas of sun exposure.

Lymph node—A bean-sized mass of tissue that is part of the immune system and is found in different areas of the body.

Lynch syndrome—A genetic syndrome causing increased cancer risks, most notably colon cancer. Also called hereditary non-polyposis colon cancer (HNPCC).

Malignant—A tumor growth that spreads to another part of the body, usually cancerous.

Mismatch repair—Repair of gene alterations due to mismatching.

Mutation—An inherited or *de novo* change in the DNA sequence of the genome.

Polyp—A mass of tissue bulging out from the normal surface of a mucous membrane.

Radiation—High-energy rays used in cancer treatment to kill or shrink cancer cells.

Sebaceous—Related to the glands of the skin that produce an oily substance.

Splenic flexure—The area of the large intestine at which the transverse colon meets the descending colon.

QUESTIONS TO ASK YOUR DOCTOR

- What are the most serious medical consequences associated with Muir-Torre syndrome?
- Are there medicines that can be taken to relieve the symptoms of Muir-Torre syndrome or to reduce their severity?
- What screening recommendations are usually made for individuals with Muir-Torre syndrome?
- What is the prognosis for a child born with this disorder, and on what factors is this prognosis based?

with multiple types of internal cancers have been reported. The most common internal organ cancer is colorectal cancer. Unlike colon cancers in the general population, the tumors due to Muir-Torre syndrome are more frequently seen around or closer to the right side of an area of the colon known as the splenic flexure. This tumor location, the meeting point of the transverse and the descending colon, is different than the usual location of colon cancer in the general population. Colon polyps (benign growths with the possibility of cancer development) have been reported in individuals with Muir-Torre syndrome; however, the number of polyps typically is limited.

Symptoms of colorectal cancer or polyps may include the following:

- red blood in stool
- weight loss
- pain or bloating in abdomen
- long-term constipation
- diarrhea
- decrease in stool size

The next most frequent cancer occurrences in Muir-Torre syndrome are those of the genitourinary system, including uterine cancer, ovarian cancer, and bladder cancer. Other cancers that have been seen with Muir-Torre syndrome include breast cancers, blood cancers, head and neck cancers, and cancers of the small intestine.

Diagnosis

Since not all families with the features of Muir-Torre syndrome have identifiable mismatch repair gene alterations, diagnosis is based mainly on the presence of the physical features of the disease. Muir-Torre syndrome is defined by the presence of certain types of sebaceous neoplasms (sebaceous adenomas, sebaceous epitheliomas, sebaceous

carcinomas, and keratoacanthomas with sebaceous differentiation) and at least one internal organ cancer in the same individual. Muir-Torre syndrome may also be diagnosed if an individual has multiple keratoacanthomas, multiple internal organ cancers, and a family history of Muir-Torre syndrome. Testing of the *MLH1* and *MSH2* genes is available and can be done to confirm a diagnosis or to assist in testing at-risk relatives prior to development of symptoms. Given the complexity of this disorder, genetic counseling may be considered before testing.

Screening recommendations have been proposed for individuals with Muir-Torre syndrome or at-risk relatives. In addition to regular screening for the skin findings, screening for internal cancers may be considered. The effectiveness of screening for individuals with or at risk for Muir-Torre syndrome has yet to be proven.

Treatment and management

While it is not possible to cure the genetic abnormality that results in Muir-Torre syndrome, it is possible to prevent and treat the symptoms of the syndrome. The skin tumors are removed by freezing or cutting. If lymph nodes, small bean-sized lumps of tissue that are part of the immune system, are involved, they must be removed also. Radiation (high energy rays) to the affected area can be beneficial. A medication, isotretinoin, may reduce the risk of skin tumors. Internal organ cancers are treated in the standard manner: removal by surgery and possible treatment with radiation or cancer-killing medication (chemotherapy). Removal of the colon (colectomy) before colon cancer develops is an option with HNPCC and may be considered for individuals with Muir-Torre syndrome.

Prognosis

The cancers associated with Muir-Torre syndrome are usually diagnosed at earlier ages than other cancers. For instance, the average age at diagnosis of colorectal cancer is ten years earlier than in the general population. Fortunately, the internal organ cancers seen in Muir-Torre syndrome appear less aggressive. Therefore, the prognosis may be better for a person with colon cancer due to Muir-Torre syndrome than colon cancer in the general population.

Multifactorial inheritance

Definition

Many common congenital malformations and diseases are caused by a combination of genetic and environmental factors. The term “multifactorial inheritance” is used to describe conditions that occur due to these multiple factors. In contrast to dominantly or recessively inherited diseases, multifactorial traits do not follow any particular pattern of inheritance in families. Multifactorial conditions do tend to cluster in families, but pedigree analysis does not reveal a specific pattern of affected individuals. Some multifactorial conditions occur because of the interplay of many genetic factors and limited environmental factors. Others occur because of limited genetic factors and significant environmental factors. The number of genetic and environmental factors vary, as does the amount of impact of each factor on the presence or severity of disease. Often there are multiple susceptibility genes involved, each of which has an additive effect on outcome.

Examples of congenital malformations following a multifactorial pattern of inheritance include cleft lip and palate, neural tube defects, and heart defects. Adult onset diseases that follow multifactorial inheritance include diabetes, heart disease, epilepsy, and affective disorders like schizophrenia. Many normal traits in the general population follow multifactorial inheritance. For instance, height, intelligence, and blood pressure are all determined

in part by genetic factors but are influenced by environmental factors.

Continuous and discontinuous traits

Some multifactorial traits are considered continuous because there is a bell-shaped distribution of those traits in the population. These are quantitative traits such as height. Other traits are discontinuous because there is a cutoff or threshold of genetic and environmental risk that must be crossed in order for the trait to occur. An example would be a malformation like a cleft lip, in which the person is either affected or unaffected. In both cases, the genetic and environmental factors that are involved in the occurrence of the condition are referred to as liability.

Pyloric stenosis

An example of a discontinuous multifactorial trait that follows the threshold model is pyloric stenosis. Pyloric stenosis is a narrowing of the pylorus, the connection between the stomach and the intestine. Symptoms of pyloric stenosis include vomiting, constipation, and weight loss. Surgery is often needed for repair. An important genetic factor in the occurrence of pyloric stenosis is a person’s gender. The condition is five times more common in males. The liability is higher in women, such that more or stronger genetic and environmental factors are needed to cause the condition in women. Therefore, male first-degree relatives of a female who is affected with pyloric stenosis have a higher risk to be born with the condition than do female first-degree relatives of the same person. This is because the stronger genetic factors present in the family (represented by the affected female) are more likely to cross the lower liability threshold in male family members.

Recurrence risks

Recurrence risks for multifactorial traits are based on empiric data, or observations from other families with affected individuals. Most multifactorial traits have a recurrence risk to first-degree relatives of 2%–5%. However, empiric data for a specific condition may provide a more specific recurrence risk. Some general characteristics about the recurrence risk of multifactorial traits include the following:

- The recurrence risk to first-degree relatives is increased above the general population risk for the trait, but the risk drops off quickly for more distantly related individuals.
- The recurrence risk increases proportionately to the number of affected individuals in the family. A person with two affected relatives has a higher risk than someone with one affected relative.

- The recurrence risk is higher if the disorder is in the severe range of the possible outcomes. For instance, the risk to a relative of a person with a unilateral cleft lip is lower than if the affected person had bilateral cleft lip and a cleft palate.
- If the condition is more common in one sex, the recurrence risk for relatives is higher in the less affected sex. Pyloric stenosis is an example of this.
- Recurrence risks quoted are averages, and the true risk in a specific family may be higher or lower.

It is important to understand that recurrence risks for conditions may vary from one population to another. For instance, North Carolina, South Carolina, and Texas all have a higher incidence of neural tube defects than other states in the United States. Ireland has a higher incidence of neural tube defects than many other countries.

Examples of multifactorial traits

Neural tube defects

Neural tube defects are birth defects that result from the failure of part of the spinal column to close approximately 28 days after conception. If the anterior (top) portion of the neural tube fails to close, anencephaly, the most severe type of neural tube defect, results. Anencephaly is the absence of portions of the skull and brain and is a lethal defect. If a lower area of the spine fails to close, spina bifida occurs. People with spina bifida have varying degrees of paralysis, difficulty with bowel and bladder control, and extra fluid in the brain called hydrocephalus. The size and location of the neural tube opening determines the severity of symptoms. Surgery is needed to cover or close the open area of the spine. When hydrocephalus is present, surgery is needed for shunt placement.

Neural tube defects are believed to follow a multifactorial pattern of inheritance. Empiric data suggests that the risk to first-degree relatives of a person with a neural tube defect is increased 3%–5%. The risk to other more distantly related relatives decreases significantly. In addition, it is known that a form of vitamin B called folic acid can significantly reduce the chance for the occurrence of a neural tube defect. Studies have shown that when folic acid is taken at least three months prior to pregnancy and through the first trimester, the chance for a neural tube defect can be reduced by 50%–70%. This data suggest that one environmental factor in the occurrence of neural tube defects is maternal folate levels. However, some women who are not folate deficient have babies with open spine abnormalities. Other women who are folate deficient do not have babies with spinal openings. The exact interplay of genetic and environmental factors in the occurrence of neural tube defects is not yet clear.

Studies are currently underway to identify genes involved in the occurrence of neural tube defects.

Diabetes

There are two general types of diabetes. Type I is the juvenile-onset form that often begins in adolescence and requires insulin injections for control of blood sugar levels. Type II is the more common, later-onset form that does not usually require insulin therapy. Both are known to be influenced by environmental factors and show familial clustering. Important environmental factors involved in the occurrence of diabetes include diet, viral exposure in childhood, and certain drug exposures. It is clear that genetic factors are involved in the occurrence of type I diabetes since empiric data show that 10% of people with the condition have an affected sibling. An important susceptibility gene for type I diabetes has been discovered on chromosome 6. The gene is called *IDDM1*. Another gene on chromosome 11 has also been identified as a susceptibility gene. Studies in mice have indicated that there are probably 12–20 susceptibility genes for insulin-dependent diabetes. *IDDM1* is believed to have a strong effect and is modified by other susceptibility genes and environmental factors.

Analysis of multifactorial conditions

Genetic studies of multifactorial traits are usually more difficult than genetic studies of dominant or recessive traits. This is because it is difficult to determine the amount of genetic contribution to the multifactorial trait versus the amount of environmental contribution. For most multifactorial traits, it is not possible to perform a genetic test to determine if a person will be affected. Instead, studies involving multifactorial traits strive to determine the proportion of the phenotype due to genetic factors and to identify those genetic factors. The inherited portion of a multifactorial trait is called heritability.

Disease association studies

One method of studying the heritability of multifactorial traits is to determine if a candidate gene is more common in an affected population than in the general population.

Sibling pair studies

Another type of study involves gathering many pairs of siblings who are affected with a multifactorial trait. Researchers try to identify polymorphisms common in the sibling pairs. These polymorphisms can then be further analyzed. Researchers can also study candidate genes in these sibling pairs. Studying individuals who are at the extreme end of the affected range and are thought to have a

larger heritability for the trait can strengthen this type of study.

Twin studies

Another approach is to study a trait of interest in twins. Identical twins have 100% of their genes in common. Non-identical twins have 50% of their genes in common, just like any other siblings. In multifactorial traits, identical twins will be concordant for the trait significantly more often than non-identical twins. One way to control for the influence of a similar environment on twins is to study twins who are raised separately. However, situations in which one or both identical twins were adopted out and are available for study are rare.

Linkage analysis and animal studies are also used to study the heritability of conditions, although there are significant limitations to these approaches for multifactorial traits.

Ethical concerns of testing

One of the goals of studying the genetic factors involved in multifactorial traits is to be able to counsel those at highest genetic risk about ways to alter their environment to minimize risk of symptoms. However, genetic testing for multifactorial traits is limited by the lack of understanding about how other genes and environment interact with major susceptibility genes to cause disease. Testing is also limited by genetic heterogeneity for major susceptibility loci. Often the attention of the media to certain genetic tests increases demand for the test, even though the limitations of the test are not fully explained. Therefore, it is important for people to receive appropriate pre-test counseling before undergoing genetic testing. Patients should consider the emotional impact of both positive and negative test results. Patients should understand that insurance and employment discrimination might occur due to test results. In addition, there may not be any treatment or lifestyle modification available for many multifactorial traits for which a genetic test is available. The patient should consider the inability to alter their risk when deciding about knowing their susceptibility for the condition. When a person chooses to have testing, it is important to have accurate post-test counseling about the result and its meaning.

Multiplex ligation-dependent probe amplification

Definition

Multiplex ligation-dependent probe amplification (MLPA) is a technique used by laboratories to detect an abnormal number of chromosomes, gene deletions, gene duplications, and gene expansions.

Description

Multiplex ligation-dependent probe amplification (MLPA) was first described by Schouten and his colleagues in 2002. The technique is designed to detect genetic issues ranging from an abnormal number of chromosomes to the location of changes in the "spelling" of genes. The technique is a multiplex assay in that it allows simultaneous testing of multiple genetic sequences.

Chromosomes are the gene-containing structures found in all of the body's cells. In each cell, there are 46 chromosomes that come in 23 pairs. Bodies are so specific that the exact amount of genetic information contained in the 46 chromosomes is required to grow and

develop properly; having any more or any less genetic information causes abnormal physical and mental growth and development.

Genes are the blueprints that carry the instructions for making all of the proteins a cell needs and determine traits, such as hair and eye color. Genes contain the inherited information that is passed on from parents to children. Each gene has a specific spelling made of the base pairs, including C, G, A, and T. If the spelling of a gene is changed, or mutated, it can cause abnormalities in the way the gene functions. Missing genetic information from the loss of one normal base pair to the loss of most of a chromosome is referred to as a deletion. A copy of genetic information that results in a redundant piece of genetic information is known as a duplication. A gene expansion refers to a genetic abnormality caused by a sequence of base pairs that is repeated too many times in a section of a gene. Detection of chromosomal abnormalities, deletions, duplications, and expansions of genetic material is an important part of diagnosing genetic conditions and diseases.

The technique of MLPA uses the spelling of the base pairs to determine if portions of chromosomes or genes are changed or mutated. The technique begins with probes that attach to the base pairs of genes and chromosomes in a specific location. The probes are divided into halves that attach around a specific gene or chromosomal location and then attach to each other. This attachment to the area around a gene or chromosome is called hybridization, and the “glue” that attaches the two probe halves to each other is the enzyme ligase. In order to help count the number of probe halves present at the end of the procedure, the probes are made in a series of different lengths. If two probe halves have properly attached to their gene or chromosomal location and each other, they serve as a target for the next step. If the probes are attached to the wrong gene area or a mismatched probe half, they will not participate in the next part of the procedure.

In the next step, a technique called polymerase chain reaction (PCR) is used to make many copies of the correctly paired and attached probe halves. The PCR will not make copies of probes attached or paired incorrectly. Finally, the properly attached and matched probes of each size are separated by size and counted. The amount of each probe size provides the information whether a small area of the gene (called an exon) or the chromosome contains a deletion, duplication, or expansion. Since there are multiple probe sizes with different gene targets, 40 or more gene exons can be tested for abnormalities at the same time.

Indications

The technique of MLPA may be indicated when a genetic condition, disease, syndrome, or disorder

KEY TERMS

Chromosomes—The gene-containing structures found in all of the body’s cells; in each normal cell, there are 46 chromosomes that come in 23 pairs.

Deletion—A mutation resulting in the loss of normal base pair sequence; a deletion may be of any size from one base pair to most of a chromosome.

Duplication—Production of one or more copies of any piece of DNA, including a base pair, gene, or entire chromosome.

Exon—Segments of a gene that contain instruction for making a protein; in many genes, the exons are separated by intervening segments of DNA, known as introns, which do not code for proteins.

Expansion—A genetic abnormality caused by a sequence of nucleotides that is repeated too many times in a section of a gene.

Genes—The basic units of heredity that contain the blueprints for the processes crucial to growth and development.

Multiplex assay—A procedure that allows the testing of several gene samples simultaneously.

Polymerase chain reaction (PCR)—A laboratory process used to make a large number of copies of specific genetic information from small amounts of DNA.

involving a chromosome abnormality, gene deletion, gene duplication, or gene amplification is suspected. Possible testing options include chromosomal disorders, such as Down syndrome; conditions caused by rearrangements of a chromosome; genetic conditions caused by gene deletions and duplications, such as Duchenne muscular dystrophy; certain forms of inherited cancer predisposition; and diseases caused by gene amplification, such as fragile X syndrome.

Samples

MLPA can be run on many bodily fluids and tissues, including blood, human embryonic stem cells, amniocytes, chorionic villi, and formalin-fixed paraffin-embedded tissue. The MLPA method requires that DNA samples obtained from the fluids and tissues be samples of uniform quality, which reduces false positives.

Results

The MLPA test can provide information about chromosomal abnormalities and gene duplications, deletions, or

expansions. If a chromosome abnormality, gene duplication, deletion, or expansion is found, it may indicate predisposition for, diagnosis of, or carrier status for a specific genetic disorder or condition.

Benefits

MLPA is a quick technique that requires a smaller amount of DNA than other testing methods. The test exhibits good sensitivity and specificity when probes are made correctly and proper reaction conditions are used. Several genetic locations can be tested in the same procedure and, accordingly, large genes made of many exons can be tested in a quick and efficient manner. Data from the technique are reproducible. DNA degradation to small fragments does not influence results, and thus testing can be done on formalin-fixed paraffin-embedded tissue.

Limitations

MLPA requires the creation of labor-intensive probes for each new gene or chromosome to be examined before the test can be run. Kits of developed probes are sold, but were not certified by the U.S. Food and Drug Administration (FDA) for use in diagnostic procedures as of 2015. The probe kits are labeled for research purposes and to demonstrate the possibilities of the MLPA technique. Accordingly, results detected through MLPA should be verified with an independent method, such as G-banding chromosome analysis or Southern blots. Although MLPA can determine the approximate location of a genetic anomaly within an exon, unless special probes for specific mutations are designed, the test cannot determine the exact mutation of base pair or pairs.

Alternative tests

There are several testing methods that provide the same information as the MLPA technique. Standard chromosome analysis, comparative genomic hybridization (CGH), fluorescent in situ hybridization (FISH), BAC arrays, Southern blots, and loss of heterozygosity (LOH) assays are used to detect chromosomal abnormalities. Some genetic mutations and expansions can be detected with multiplex polymerase chain reaction (PCR) assays, fluorescent in situ hybridization (FISH), and/or Southern blotting.

Multiple endocrine neoplasia

Definition

Multiple endocrine neoplasia (MEN) is a group of related disorders affecting the thyroid and other endocrine glands (glands that secrete hormones into the bloodstream) of the body. Mutations in three separate genes are associated with the development of MEN. MEN was previously known as familial endocrine adenomatosis.

All MEN disorders are associated with the development of neuroendocrine tumors. These tumorous cells have in common the fact that they produce hormones, or regulatory substances for the body's homeostasis. They come from the amine precursor and uptake decarboxylase (APUD) system, and they have to do with the cell apparatus and function to make these substances common to the cell line. Neuroendocrine tumors cause syndromes associated with each other by genetic predisposition.

Description

The three forms of MEN are MEN1 (Wermer's syndrome); MEN2, which includes three subgroups—MEN2A (Sipple syndrome), MEN2B (previously known as MEN3), and familial medullary thyroid carcinoma (FMTC); and MEN4. Each is an autosomal dominant genetic condition, and all except FMTC predispose to hyperplasia (excessive growth of cells) and tumor formation in a number of endocrine glands. FMTC predisposes only to this specific type of thyroid cancer.

Association of multiple endocrine neoplasias with other conditions

Form	Inheritance	Associated diseases/conditions	Affected gene
MEN 1 (Wermer's syndrome)	Autosomal dominant	Parathyroid hyperplasia Pancreatic islet cell carcinomas Pituitary hyperplasia Thymus, adrenal, carcinoid tumors (less common)	MEN 1
MEN 2A (Sipple syndrome)	Autosomal dominant	Medullary thyroid carcinoma Pheochromocytoma Parathyroid hyperplasia	RET
MEN 2B	Autosomal dominant	Medullary thyroid carcinoma Pheochromocytoma Parathyroid hyperplasia Swollen lips Tumors of mucous membranes (eyes, mouth, tongue, nasal cavities) Enlarged colon Skeletal problems such as spinal curving	RET
Familial medullary thyroid carcinoma	Autosomal dominant	Medullary thyroid carcinoma	RET

(Gale)

MEN1 predisposes affected individuals to more than 20 benign and malignant endocrine and non-endocrine neoplasias. Individuals with MEN1 experience hyperplasia (increased reproduction of cells that is often the first stage in the development of malignancies) of the parathyroid glands and may develop tumors of several endocrine glands, including the pancreas and pituitary. The most frequent symptom of MEN1 is hyperparathyroidism. Hyperparathyroidism results from overgrowth of the parathyroid glands, leading to excessive secretion of parathyroid hormone, which in turn leads to elevated blood calcium levels (hypercalcemia), kidney stones, weakened bones, fatigue, and weakness. Almost all individuals with MEN1 show parathyroid symptoms by age 50, with some individuals developing symptoms in childhood.

About 40% to 70% of individuals with MEN1 develop a pancreatic tumor, called a pancreatic islet cell carcinoma. These tumors tend to be benign, although occasionally they may become malignant and spread. The pancreatic tumors associated with MEN1 may be non-functional tumors (no increase in hormone production and, consequently, no symptoms) or functional tumors where hormone production is increased, resulting in symptoms; the symptoms depend upon the hormone produced. The most common functional tumor is gastrinoma, followed by insulinoma. Other less-frequent functional tumors are VIPoma and glucagonoma. Gastrinoma results in excessive secretion of gastrin (a hormone secreted into the stomach to aid in digestion), which in turn may cause upper gastrointestinal ulcers; this condition is sometimes referred to as Zollinger-Ellison syndrome. About one in three people with MEN1 develops a gastrinoma. Insulinoma causes an increase in insulin levels, which in turn causes glucose levels to decrease.

This tumor causes symptoms consistent with low glucose levels (hypoglycemia, low blood sugar), which include anxiety, confusion, tremor, and seizure during periods of fasting. The pituitary may also be affected, resulting in extra production of hormone. The most frequent of these is prolactinoma, which results in extra production of prolactin, which affects bone strength and fertility. Less commonly, the thymus and adrenal glands may also be affected, and in rare cases a tumor called a carcinoid may develop. Unlike MEN2, the thyroid gland is rarely involved in MEN1 symptoms.

Patients with MEN2A experience two main symptoms: medullary thyroid carcinoma (MTC) and a tumor of the adrenal gland known as pheochromocytoma. Medullary thyroid carcinoma is a slowly growing cancer that is preceded by a condition called C-cell hyperplasia. C-cells are cells within the thyroid gland that produce a hormone called calcitonin. About 40% to 50% of individuals with MEN2A develop C-cell hyperplasia followed by MTC by the time they are 50 years old, and 70% will have done so by the time they are 70 years old. In some cases, individuals develop C-cell hyperplasia and MTC in childhood. Medullary thyroid carcinoma tumors are often multifocal and bilateral.

Pheochromocytoma is usually a benign tumor that causes excessive secretion of adrenal hormones, which in turn can cause life-threatening hypertension (high blood pressure) and cardiac arrhythmia (abnormal heart rate and rhythm). About 40% of people with MEN2A develop a pheochromocytoma. Individuals with MEN2A also have a tendency for the parathyroid gland to increase in size (hypertrophy), and they may develop tumors in the parathyroid gland. About 25% to 35% of individuals with MEN2A will develop parathyroid involvement.

Individuals with MEN2B also develop MTC and pheochromocytoma. However, the medullary thyroid carcinomas often develop at much younger ages—often before the age of one year—and they tend to be more aggressive tumors. About half of the individuals with MEN2B develop a pheochromocytoma, with some cases diagnosed in childhood. All individuals with MEN2B develop additional conditions, which make it distinct from MEN2A. These extra features include a characteristic facial appearance with swollen lips; tumors of the mucous membranes of the eye, mouth, tongue, and nasal cavity; enlarged colon; and skeletal abnormalities, such as long bones and problems with spinal curving. Hyperparathyroidism is not seen in MEN2B as it is in MEN2A. Unlike the other three MEN syndromes, individuals with MEN2B might not have a family history of MEN2B. In at least half of the cases, the condition is new in the individual affected.

Medullary thyroid carcinoma may also occur in families, but family members do not develop the other endocrine conditions seen in MEN2A and MEN2B. This is referred to as familial medullary thyroid carcinoma (FMTC) and is a subtype of MEN2. Familial medullary thyroid cancer is suggested when other family members have also developed MTC, if the tumor is bilateral, and/or if it is multifocal. In comparison to MEN2A and MEN2B, individuals with FMTC tend to develop MTC at older ages, and the disease appears to be more indolent or slow to progress. About 25% of MTC occurs in individuals who have MEN2A, MEN2B, and FMTC.

MEN4 was identified through the observation that 5% to 10% of patients with MEN1 syndrome do not have a corresponding mutation in the *MEN1* gene. Research using a rat model system of MEN-like symptoms called MENX resulted in the identification of the link between MENX and mutations in the *rCDNK1B* gene. Further investigation of the MEN1 patients without the *MEN1* gene mutation determined that 3% of these individuals carried a mutation in the *CDNK1B* gene. Individuals affected with MEN4 exhibit the hyperparathyroidism and *MEN1*-associated tumors, such as parathyroid adenomas, pituitary adenomas, and pancreatic neuroendocrine tumors (NETs) in association with gonadal, adrenal, renal, and thyroid tumors.

Genetic profile

All three MEN syndromes follow autosomal dominant inheritance, meaning that every individual diagnosed with a MEN syndrome has a 50% (one in two) chance of passing the condition on to each of his or her children.

MEN1 results from alterations or mutations in the *MEN1* gene located on chromosome 11q13. Nearly every individual inheriting the *MEN1* gene alteration will develop hyperparathyroidism, although the age at which it is diagnosed may differ among family members. Individuals inheriting the familial mutation may also develop one of the other characteristic features of MEN1; however, this often differs among family members as well.

The three subtypes of MEN2 are caused by mutations in another gene known as *RET* located on chromosome 10q11.2. Every individual who inherits a *RET* mutation will develop MTC during his or her lifetime, although the age at the time of diagnosis is often different in each family member. Multiple different mutations have been identified in individuals and families who have MEN2A. Likewise, several different mutations have been identified in individuals and families with FMTC. One interesting finding has been that a few families who clearly have MEN2A and a few families who clearly have FMTC have the same mutation. The reason the families developed different clinical features is not yet known. In contrast to MEN2A and FMTC, individuals with MEN2B have been found, in more than 90% of cases, to have the same *RET* mutation. This mutation is located in a part of the gene that has never been affected in individuals and families with MEN2A and FMTC.

The difference between MEN1 and MEN4 is the germline gene mutation. MEN4 shares an overlapping phenotype with MEN and results from alterations or mutations in the *CDKN1B* gene located on chromosome 12p13.1-p12. MEN4 has been associated with hyperparathyroidism and the development of parathyroid and pituitary adenoma, reproduction organ tumors (e.g., testicular cancer, neuroendocrine cervical carcinoma), and adrenal and renal tumors.

Demographics

MEN syndromes are rare. It has been estimated that MEN1 occurs in three to 20 out of every 100,000 people. MEN syndromes affect both men and women, and they occur worldwide. The incidence of MEN2 has not been published, but it has been reported that MEN2B is far less common than MEN2A. Because very few cases of MEN4 have been reported, and many remain undiagnosed, the precise incidence and prevalence of MEN4 are uncertain. Similarly, as of 2021, the age of onset of disease in MEN4 remains unclear.

Signs and symptoms

General symptoms of the characteristic features of the MEN syndromes and their causes include the following:

- Hyperparathyroidism, which may or may not cause symptoms. Symptoms that occur are related to the high levels of calcium in the bloodstream such as kidney stones, fatigue, muscle or bone pain, indigestion, and constipation.
- Medullary thyroid carcinoma may cause diarrhea, flushing, and depression.
- Pheochromocytoma may cause a suddenly high blood pressure and headache, palpitations or pounding of the heart, a fast heartbeat, excessive sweating without exertion, and/or development of these symptoms after rising suddenly from bending over.

Diagnosis

In the past, diagnosis of the MEN syndromes depended on clinical features and laboratory test results. Since the genes responsible for these conditions were identified, genetic testing provides another means of diagnosing individuals and families with these conditions. However, all of these tumors have a higher incidence of sporadic cases. It is important to ask patients about family members when one of these types of tumor is diagnosed.

MEN1 and MEN4 are typically diagnosed from clinical features and from testing for parathyroid hormone (PTH). Elevated PTH indicates that hyperparathyroidism is present. When an individual develops a MEN1-related symptom or tumor, a complete family history should be obtained. If no family history of MEN1 or related problems such as kidney stones and peptic ulcers exists, and close family members (i.e., parents, siblings, and children) have normal serum calcium levels, then it is unlikely that the person has MEN1. However, if the individual is found to have a second symptom or tumor characteristic of MEN1, the family history is suggestive of MEN1, and/or close family members have increased serum calcium levels, then MEN1 may be the correct diagnosis.

Genetic testing for the *MEN1* gene has helped to evaluate individuals and families for MEN1. If an individual apparently affected by MEN1 is found to have a mutation in the *MEN1* gene, then this positive test result confirms the diagnosis, while identification of a mutation in the *CDKN1B* gene is a diagnostic of MEN4. However, genetic testing of the *MEN1* and *CDKN1B* genes does not identify all mutations causing MEN1; consequently, a negative test result does not rule out the diagnosis. In up to 30% of MEN1 patients diagnosed based on clinical criteria, MEN1 mutations are not identified. Identification of susceptibility genes for endocrine tumor syndromes that have at least one common feature with MEN1 has helped to extend the genetic diagnosis of MEN1 mutation-negative cases to include those additional genes in the

KEY TERMS

Bilateral—Relating to or affecting both sides of the body or both of a pair of organs.

Endocrine glands—A system of ductless glands that regulate and secrete hormones directly into the bloodstream.

Hormone—A chemical messenger produced by the body that regulates specific bodily functions such as growth, development, and reproduction.

Hyperplasia—An overgrowth of normal cells within an organ or tissue.

Magnetic resonance imaging (MRI)—A diagnostic procedure that uses a combination of high-powered magnets, radio frequencies, and computers to generate detailed images of structures within the body.

Medullary thyroid cancer (MTC)—A slowly growing tumor associated with MEN.

Multifocal—A pathological term meaning that instead of finding one tumor in the tissue, multiple tumors are found.

Neoplasm—An abnormal growth of tissue; for example, a tumor.

Parathyroid glands—A pair of glands adjacent to the thyroid gland that primarily regulates blood calcium levels.

Pheochromocytoma—A small vascular tumor of the inner region of the adrenal gland. The tumor causes uncontrolled and irregular secretion of certain hormones.

Pituitary gland—A small gland at the base of the brain that is responsible for releasing many hormones, including luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

Thyroid gland—A gland located in the front of the neck that is responsible for normal body growth and metabolism. The thyroid traps a nutrient called iodine and uses it to make thyroid hormones, which allow for the breakdown of nutrients needed for growth, development, and body maintenance.

Ultrasound examination—A procedure that examines the tissue and bone structures of an individual or a developing baby.

genetic testing. Accurate identification is important, since research reported in 2021 indicates that individuals with MEN1 who are genotype positive have a different clinical course from those who are genotype negative.

MEN2A is typically diagnosed from clinical features and laboratory testing of calcitonin levels. Elevated calcitonin levels indicate that C-cell hyperplasia and/or MTC is present. When an individual develops a MEN2A-related symptom or tumor, a complete family history should be obtained. If no family history of related problems exists, and close family members (i.e., parents, siblings, and children) have normal calcitonin levels, then it is unlikely that the person has MEN2A. However, if the individual is found to have a second symptom or tumor characteristic of MEN2A, the family history is suggestive of MEN2A, and/or close family members have increased calcitonin levels, then MEN2A may be the correct diagnosis.

Genetic testing for the *RET* gene has helped with evaluating an individual and/or family for MEN2A. If an individual apparently affected by MEN2A is found to have a mutation in the *RET* gene, then this positive test result confirms the diagnosis. Genetic testing of the *RET* gene does not identify all mutations causing MEN2A and FMTC; consequently, a negative test result does not rule out the diagnosis.

Diagnosis of MEN2B can be made by physical examination and a complete medical history.

Diagnosis of FMTC can be made when the family history includes four other family members who have developed MTC with no family member who has developed a pheochromocytoma or pituitary tumor. Genetic testing of the *RET* gene may also assist with diagnosis.

Genetic testing of the *MEN1* gene and of the *RET* gene allows individuals to be diagnosed prior to the onset of symptoms; this is often called predictive genetic testing. It is important to note that individuals should not undergo predictive genetic testing prior to the identification of the familial genetic mutation. Genetic testing of a family member who is clinically affected by the condition needs to be performed first in order to identify the familial mutation. If that is not done, a negative result in an asymptomatic individual might not be a true negative test result.

Prenatal diagnosis of unborn babies is now technically possible via amniocentesis or chorionic villus sampling (CVS). However, prior to undergoing these procedures, the familial mutation needs to have been identified. One additional issue in prenatal diagnosis is how the test result will be used with regard to continuation of the pregnancy. Individuals considering prenatal diagnosis of MEN1 or MEN2 should confirm its availability prior to conception.

Genetic testing is best done in consultation with a geneticist (a doctor specializing in genetics) and/or a genetic counselor.

QUESTIONS TO ASK YOUR DOCTOR

- What are the most serious medical consequences associated with MEN?
- Are there medicines that can be taken to relieve the symptoms of MEN to reduce their severity?
- What screening recommendations are usually made for individuals with MEN syndrome?
- What is the prognosis for a child born with this disorder, and on what factors is this prognosis based?

Treatment and management

No cure or comprehensive treatment is available for the MEN syndromes. However, some of the consequences of the MEN syndromes can be symptomatically treated, and complications may be lessened or avoided by early identification.

For individuals affected by MEN1 and MEN4, hyperparathyroidism is often treated by surgery. The parathyroids may be partially or entirely removed. If they are entirely removed, the individual will need to take calcium and vitamin D supplements. Pancreatic tumors that develop may also be removed surgically, or pharmacological treatment (medication) may be given to provide relief from symptoms. The pituitary tumors that develop may not require treatment, but if they do, medication is often effective. Surgery and radiation are used in rare cases.

Children of an individual affected by MEN1 and MEN4 should begin regular medical screening in childhood. It has been suggested that beginning at five to ten years of age, children have annual measurements of serum calcium; serum prolactin; and the pancreatic, pituitary, and parathyroid hormones. Children should also undergo radiographic imaging (ultrasound, MRI examination) of the pancreas and pituitary. When the family history indicates the development of symptoms at younger-than-usual ages, the children may need to begin medical screening earlier.

For the three types of MEN2, the greatest concern is the development of medullary thyroid carcinoma. Medullary thyroid carcinoma can be detected by measuring levels of the thyroid hormone, calcitonin. Treatment of MTC is surgical removal of the thyroid and the neighboring lymph nodes, although doctors may disagree about which stage to remove the thyroid. After thyroidectomy,

the patient will receive normal levels of thyroid hormone orally or by injection. Even when surgery is performed early, metastatic spread of the cancer may have already occurred. Since this cancer is slowly growing, metastasis may not be obvious. Metastasis is very serious in MTC, because chemotherapy and radiation therapy are not effective in controlling its spread.

In the past, children who had a parent affected by one of the MEN2 syndromes were screened for MTC by annual measurement of calcitonin levels. More recently, it has been determined that MTC can be prevented by prophylactic thyroidectomy, meaning that the thyroid gland is removed before it is obviously affected by cancer. It is not uncommon for a child as young as one year of age (when the family history is of MEN2B) or six years of age (when the family history is of MEN2A or FMTC) to undergo prophylactic thyroidectomy in order to prevent the occurrence of MTC.

Pheochromocytomas that occur in MEN2A and MEN2B can be cured by surgical removal of this slowly growing tumor. Pheochromocytomas may be screened for using annual abdominal ultrasound or CT examination and laboratory testing. For individuals diagnosed with MEN2, it is also recommended that the pituitary be screened by laboratory tests.

In general, each tumor may be approached surgically. Problems occur when the tumors are multiple, when the whole gland is involved (hyperplasia as opposed to tumor), when replacement therapy is difficult (pituitary or adrenal), or when the gland makes multiple hormones. (If the gland is removed, hormone replacement therapy becomes necessary.)

Prognosis

Diagnosed early, the prognosis for the MEN conditions is reasonably good, even for MEN2B, the most dangerous of the forms. Individuals with MEN1 may have a shorter life expectancy, because the numbers and aggressiveness of their tumors may impair the effectiveness of treatment. The prognosis is better when tumors are detected before they become symptomatic. Since 1997, when the MEN1 gene was identified, genetic screening has enabled clinicians to anticipate the diagnosis of MEN1 in asymptomatic carriers more than 10 years before the appearance of signs of the disease. Some epigenetic factors, including microRNAs (miRNAs), single-stranded non-coding small RNAs that negatively regulate gene expression, have been associated with MEN1 tumor development. Research is underway to determine whether the involvement of miRNAs in MEN1 tumor development makes them useful prognostic biomarkers and targets for molecular therapies.

Medullary thyroid cancer can be cured when identified early. Ideally, the availability of genetic testing to identify family members at risk for developing the conditions will lead to earlier treatment and improved outcomes.

Multiple epiphyseal dysplasia

Definition

Multiple epiphyseal dysplasia (MED) is a hereditary disorder characterized by abnormal epiphyses (bone extremities) that lead to early-onset joint pain and recurrent inflammation of cartilage and bone. There are five subtypes of MED, each with varying clinical manifestations and inheritance patterns.

Description

Multiple epiphyseal dysplasia (MED) is a hereditary condition characterized by abnormal development of cartilage and bone. The epiphysis is the portion at the end of a long bone where growth occurs. Dysplasia is an abnormality in development leading to alteration in size, shape, and organization of cells. Thus, in MED, the epiphyses of the long bones are dysplastic and joint pain and inflammation result. On x-ray, the epiphyses appear flattened and irregular. Cartilage in the joints becomes irregular and this leads to early-onset osteoarthritis. Patients often have short hands and stubby fingers.

MED can be divided into five subtypes, four of which are inherited in an autosomal dominant fashion (EDM1, EDM2, EDM3, and EDM5) and one of which is inherited in an autosomal recessive fashion (EDM4). All of the subtypes are characterized by early-onset joint pain, most often in the hips and knees. Most individuals with MED have adult heights that are in the low range of normal, although some may have slightly short stature.

Dominant MED

Dominant MED was initially divided into two forms: a mild form, called Ribbing disease, and a more severe form, called Fairbank disease. Dominant MED has been further classified into four subtypes to accommodate the extreme clinical variability that exists. In addition to hip and knee pain and occasional short stature, individuals with dominant MED may have a waddling gait and their limbs may be relatively short when compared to the trunk. Joint pain and deformity become worse with age in these patients and early-onset osteoarthritis is often a problem, especially in the large, weight-bearing joints.

Recessive MED

Recessive MED is also known as EDM4 and rMED. In addition to early-onset joint pain and possible short stature, this disorder is associated with scoliosis (curvature of the spine), as well as malformations of the hands, feet, and knees. Some affected individuals may also present with a clubfoot or an abnormality of the kneecap, called a double-layered patella. This finding is very suggestive of recessive MED.

Genetic profile

Dominant MED

Mutations in five different genes have been associated with dominant MED:

- EDM1 is caused by mutations in the *COMP* gene, which codes for the cartilage oligomeric matrix protein. This gene is also responsible for the more severe disorder, called pseudoachondroplasia.
- EDM2 and EDM3 result from mutations in two of the three genes that code for the protein chains of type IX collagen. *COL9A2* mutations lead to EDM2 and *COL9A3* mutations lead to EDM3. Mutations in these genes can also lead to lumbar/intervertebral disk disease (IDD), which is a very common musculoskeletal disorder.
- Defects in the matrilin 3 protein, caused by mutations in the *MATN3* gene, lead to a diagnosis of EDM5. Matrilin 3 plays a key role in the cartilage extracellular matrix.

Extreme variability in clinical manifestations can be seen both between and within families with mutations in the various genes responsible for dominant MED.

EDM1, EDM2, EDM3, and EDM5 are all dominant forms of MED and are inherited in an autosomal dominant pattern. Thus, the majority of affected individuals have a parent that is affected as well. However, this is not always the case as there may be a new (*de novo*) mutation in the affected individual that was not present in either parent. Additionally, there may appear to be a lack of family history due to the affected parent dying at a young age or the failure to recognize symptoms of the disorder in a parent. Asymptomatic parents of affected individuals should be given a careful clinical and radiographic examination to completely rule out any signs of the disorder.

Most often, one parent of the affected individual will have signs of dominant MED and/or a disease-causing mutation. In this case, siblings of the affected individual have a 50% chance of inheriting the same mutation and being affected as well. However, if a mutation is identified in the affected individual and both parents test

negative for this mutation, it is likely that the gene mutation is *de novo* and, therefore, recurrence risk to siblings is very low. The prevalence of *de novo* mutations in dominant MED is unknown.

Another possibility is germline mosaicism. In this case, the gene mutation may be present only in the egg cells of the mother or the sperm cells of the father. Thus, the parent will not show signs of the disorder, since the gene mutation is confined to the sex cells. However, the mutations present in the egg or sperm would leave a significant recurrence risk for future pregnancies.

No matter how the affected individual inherits the gene mutation, each of his or her children has a 50% chance to inherit the disease-causing mutation and, therefore, be affected with dominant MED.

Recessive MED

Recessive MED is caused by mutations in the *SLC26A2* gene, also known as *DTDST*. Mutations in this gene cause a spectrum of skeletal disorders of which recessive MED is the mildest. *SLC26A2* codes for a protein that plays a key role in the normal development of cartilage and its conversion to bone. When the *SLC26A2* gene is mutated, cartilage cannot develop properly and, as a result, bones do not form correctly and skeletal problems result.

As implied by its name, recessive MED is inherited in an autosomal recessive manner. This means that an affected individual will have two abnormal copies of the *SLC26A2* gene in each cell. Most often, the parents of an affected individual each carry a mutation on one of their two copies of the *SLC26A2* gene. Mutation carriers do not show signs or symptoms of recessive MED. Siblings of affected individuals have a 25% chance of being affected with the disorder and a 50% chance of being carriers of the disorder. Offspring of an affected individual will be obligate carriers of an *SLC26A2* gene mutation, but will not show signs or symptoms of the disorder.

Demographics

Dominant MED

Dominant MED is thought to present in at least 1 in 10,000 births. Due to the clinical variability and range of severity associated with the disorder, it is likely that many individuals have yet to be diagnosed. There are no reports of the condition being more common in specific ethnic groups or geographical regions.

Recessive MED

The prevalence of recessive MED was unknown as of 2015. There are no reports of the condition being more

common in specific ethnic groups or geographical regions. Due to the mild signs and symptoms of the disorder, it is likely that the disease is underdiagnosed and is more common than once thought.

Signs and symptoms

Dominant MED

Dominant MED often presents in early childhood with pain in the hips and/or knees. Affected patients often complain of this pain, accompanied by fatigue, after physical activity. Over time, this pain progressively worsens, joints become deformed, and early osteoarthritis results, most often in the large, weight-bearing joints. In some cases, joint replacement may be necessary.

Individuals with dominant MED may walk with a waddling gait. Restriction in the range of motion in the elbows is apparent in many cases, as is hypermobility in the knee and finger joints. Characteristic radiographic findings of dominant MED include abnormalities of the epiphyses of the long tubular bones, especially in the hips and/or knees. These abnormalities are due to delayed ossification and manifest as small and irregular ossification centers. This finding may be present very early, even before other clinical signs and symptoms are evident. Later, in adulthood, signs of osteoarthritis can be seen on x-rays and the tubular bones may be slightly shortened. The spine is generally not involved in dominant MED. Adult height may be slightly shorter than normal and the limbs are often short relative to the trunk. Intelligence is normal.

There are various clinical manifestations that distinguish the subtypes of dominant MED:

- EDM1 is characterized by mild to moderate short stature and the limbs are usually short when compared to the trunk. Individuals with EDM1 may have minor spine irregularities that can be seen on x-ray, but nothing as severe as the scoliosis associated with EDM4. The fingers and metacarpals (bones from the wrists to the fingers) are usually shortened. The main complication of this subtype is early arthritis of the hip.
- EDM2 and EDM3 are associated with mild short stature. There is more severe knee involvement in these subtypes and hip problems are often less severe. The courses of EDM2 and EDM3 are milder than EDM1 and EDM4. In EDM2, the hands are somewhat short but in EDM3, they tend to be normal with shortened metacarpals.
- EDM5 is the mildest form of MED. Affected patients usually have normal stature and less severe involvement of joints. Mild abnormalities in the pelvis seem to be more common in this subtype compared to the others.

Recessive MED

Approximately 50% of individuals affected with recessive MED show signs or symptoms of the disorder at birth. Examples include clubfoot, cleft palate, ear swelling, or clinodactyly (a condition where the little finger is curved towards the ring finger). Joint pain in the hips and knees is very common in affected individuals and most often onsets in late childhood. However, this pain may begin at various times in different individuals and is not always present. Individuals affected with recessive MED are of normal stature, although some may be slightly shorter than expected in adulthood. As in dominant MED, intelligence is normal.

Affected individuals tend to have characteristic facial features, such as anteverted nares (nasal passages) and a round, flat face. They may also be myopic (nearsighted). Malformations of the hands, feet, and knees are very common. These may include brachydactyly (abnormal shortness) of toes and fingers, small hands/feet, and absent/small fingernails. A double-layered patella (kneecap) is found in 60% of patients and is very suggestive of recessive MED. This finding seems to be age-dependent and may disappear when the affected individual reaches adulthood. Scoliosis is fairly common in affected individuals as well and this finding distinguishes recessive MED from dominant forms of MED. Occasionally, recessive MED may be associated with sensorineural deafness, hip anomalies, wrist anomalies, or delayed bone age.

Diagnosis

Dominant MED

Clinical and radiographic findings of the patient and family members can assist in the diagnosis of dominant MED. Even before the onset of clinical signs and symptoms, x-rays often show delayed ossification of the epiphyses of the long tubular bones. This delayed ossification is usually most noticeable in the hips and/or knees. Additionally, the x-rays may show slightly shortened long tubular bones. Radiographic diagnosis of MED is often difficult, if not impossible, in adults. Thus, x-rays should be completed in childhood, if possible. Due to the autosomal dominant pattern of inheritance, there are usually multiple family members affected with the disorder.

Molecular genetic testing can be used to confirm a diagnosis of dominant MED in a patient with characteristic clinical and radiographic features. Sequence analysis is available to analyze all five genes implicated in dominant MED. Mutations are found in the *COMP* gene in approximately 35% of cases, in the *MATN3* gene in

KEY TERMS

Amniocentesis—A prenatal test in which a hollow needle is inserted through the abdominal wall and into the uterus of a pregnant female in order to obtain amniotic fluid, which contains cells from the fetus. These cells can be examined to determine the sex of the fetus or to look for genetic diseases.

Chorionic villus sampling (CVS)—Biopsy of the placenta through the abdominal wall or by way of the vagina and uterine cervix to obtain fetal cells for the prenatal diagnosis of a genetic disorder.

Osteoarthritis—A disease of the cartilage in joints that causes progressive breakdown of cartilage until the bones, which were once separated by cartilage, rub against each other. This results in damage to the tissue and underlying bone, causing joint pain.

Radiographic—Involving an x-ray.

approximately 10% of cases, and in the *COL9A2* and *COL9A3* genes in less than 5% of cases. However, in about 50% of individuals with clinical and radiographic features consistent with dominant MED, no mutation can be found by molecular genetic testing. Thus, it is believed that other unidentified genes are likely responsible for this disorder. However, there are other conditions that can result from mutations in some of these genes (namely, *COMP*, *COL9A2*, and *COL9A3*). The type of disorder that results depends on the type of mutation in the gene. Thus, genetic test results must be interpreted based on clinical and radiographic findings.

Prenatal diagnosis for at-risk pregnancies is possible via molecular genetic testing, but is not commonly requested. Once a disease-causing mutation has been found in a family, fetal cells obtained by chorionic villus sampling (CVS) or amniocentesis can be analyzed for this mutation to determine the mutation status of the fetus.

Recessive MED

A diagnosis of recessive MED is based on clinical and x-ray findings during childhood or early in adult life. The disorder is suspected when an autosomal recessive pattern of inheritance is seen and when characteristic signs and symptoms are noted, such as hip and knee pain; malformations of hands, feet, and knees; and scoliosis. X-rays may show flat epiphyses with early arthritis, mild brachydactyly, and the characteristic double-layered patella.

The diagnosis of recessive MED can be confirmed via molecular genetic testing of the *SLC26A2* gene. A mutation is found in approximately 70% of patients who are suspected to have the disorder based on clinical and radiographic features. Interestingly, mutations were found in 100% of patients with double-layered patella, which is a very specific sign for recessive MED. There are three common mutations in the *SLC26A2* gene that account for approximately 90% of genetically characterized cases of recessive MED. Thus, molecular genetic testing often begins with analysis for these three mutations. It can be followed by full gene sequence analysis if necessary. There are three other autosomal recessive skeletal dysplasias that can result from mutations in the *SLC26A2* gene. The type of disorder that results depends on the severity of the genetic mutations in the gene. Thus, genetic test results must be interpreted based on clinical and radiographic findings.

Carrier testing for at-risk family members who do not show any clinical signs of the disorder is available once the *SLC26A2* gene mutations have been identified in an affected individual. Carrier detection in reproductive partners of *SLC26A2* gene carriers is available as well. If a mutation is found in a reproductive partner, details about the severity of that mutation should be provided due to the fact that various *SLC26A2* mutations can lead to various genetic conditions.

Prenatal diagnosis for at-risk pregnancies is possible in the same manner as dominant MED.

Treatment and management

Dominant MED

The goal for patients with dominant MED is to decrease pain, restrict joint destruction, and prevent the development of osteoarthritis. Pain is often difficult to control in affected individuals. However, analgesics (that is, nonsteroidal anti-inflammatory drugs) and physiotherapy have been shown to be effective in some cases. An orthopedic surgeon can advise patients on whether surgical procedures (that is, realignment osteotomy or acetabular osteotomy) might slow the progression of symptoms. In some patients, joint replacement may be necessary. Affected patients should avoid obesity and activities that strain affected joints.

Recessive MED

Individuals with recessive MED should be seen by an orthopedist who can assess the possibility of treatment. This may include physiotherapy for the purpose of strengthening muscles, use of analgesics (i.e., nonsteroidal anti-inflammatory drugs), and the timing of surgery, if

necessary. As in dominant MED, affected patients should avoid obesity and activities that strain affected joints.

Prognosis

Patients with dominant and recessive MED have a normal life expectancy and generally lead productive and healthy adult lives.

Multiple lentigines syndrome

Definition

Multiple lentigines syndrome is a rare genetic condition that causes the affected individual to have many dark

brown or black freckle-like spots on the skin, as well as other symptoms.

Description

Multiple lentigines syndrome is a genetic disorder that results in characteristic marking of the skin, abnormalities in the structure and function of the heart, hearing loss, wide-set eyes, and other symptoms. Other terms for multiple lentigines syndrome include cardiomyopathic lentiginosis and LEOPARD syndrome. LEOPARD syndrome is an acronym for the seven most commonly observed symptoms of the disorder:

- (L)entigines, or small dark brown and black spots on the skin
- (E)lectrocardiographic conduction defects, or abnormalities of the muscle activity in the heart
- (O)cular hypertelorism, or eyes that are spaced farther apart than normal
- (P)ulmonary stenosis, or narrowing of the lower right ventricle of the heart
- (A)bnormalities of the genitals, such as undescended testicles or missing ovaries
- (R)etarded growth leading to shortness of stature
- (D)eafness or hearing loss

The lentigines observed in multiple lentigines syndrome are similar in size and appearance to freckles, but unlike freckles they are not affected by sun exposure. The disorder was first described in 1936 with a limited number of syndromes including lentigines, ocular hypertelorism, and abnormal development of the breast and jaw bones. In the 1960s the disorder was further characterized to include the additional symptoms that are known today.

Genetic profile

Multiple lentigines syndrome is inherited as an autosomal dominant trait. Autosomal means that the syndrome is not carried on a sex chromosome, while dominant means that only one parent has to pass on the gene mutation in order for the child to be affected with the syndrome.

LEOPARD syndrome is part of a family of syndromes caused by mutations in the Ras/MAPK pathway; multiple lentigines syndrome is caused by mutations in the genes for on-receptor type 11 (*PTPN11*), which encodes for a protein tyrosine phosphatase that removes phosphates from tyrosine molecules; Raf-1 proto-oncogene, serine/threonine kinase (*RAF1*); and B-Raf proto-oncogene, serine/threonine kinase (*BRAF*). All of these genes encode kinase proteins that are important for signal pathways required for the formation and

KEY TERMS

Lentigo (plural, lentigines)—A dark colored spot on the skin.

Scoliosis—Abnormal curvature of the spine, usually defined as greater than ten degrees to the right or left as the doctor faces the patient.

Stenosis—The constricting or narrowing of an opening or passageway.

development of several types of tissues. These pathways include regulation of cell division, cell migration, and cell differentiation. In cases of multiple lentigines syndrome, approximately 90% are due to mutations in *PRPN11*, and the other 10% are caused by mutations in the *RAF1* and *BRAF* genes.

Demographics

Multiple lentigines syndrome is extremely rare, and due to the small number of reported cases, demographic trends for the disease have not been established. There does not seem to be any clear ethnic pattern to the disease. Both males and females appear to be affected with the same probability.

Signs and symptoms

The most characteristic symptom of the disease is the presence of many dark brown or black spots, ranging in size from barely visible to 2.5 in. (5 cm) in diameter all over the face, neck, and chest. They may also be present on the arms and legs, genitalia, palms of the hands, and soles of the feet. The spots appear in infancy or early childhood and become more numerous until the age of puberty. There may also be lighter brown birthmarks on the skin.

Heart defects, such as the pulmonary stenosis and electrocardiographic conduction abnormalities, are another hallmark of multiple lentigines syndrome. Other narrowing (stenosis) in different areas of the heart may be present, as well as abnormalities in the atrial septum, or the wall between the upper left and right chambers of the heart. There is an increased risk of heart disease and tumors of the heart in people with multiple lentigines syndrome.

Other features can include widely spaced eyes, low-set or prominent ears, drooping eyelids, a short neck, or a projecting jaw. In some cases of multiple lentigines syndrome, additional skeletal malformations have been reported, including a sunken breastbone, rib anomalies,

QUESTIONS TO ASK YOUR DOCTOR

- Why is multiple lentigines syndrome also called LEOPARD syndrome?
- At what stage in fetal or child development can multiple lentigines syndrome be diagnosed?
- What tests or other procedures are used to diagnose this condition?
- Can multiple lentigines syndrome be cured and, if not, what kinds of treatment are available?

curvature of the spine (scoliosis), and webbing of the fingers.

Deafness or hearing loss is observed in about 25% of the cases of multiple lentigines syndrome. Some people affected with the syndrome also exhibit mild developmental delays. Other reported neurological findings include seizures, eye tics, and abnormal electrical activity in the brain.

People with multiple lentigines syndrome often exhibit genital abnormalities such as undescended testicles or a small penis in men, or missing or underdeveloped ovaries in women. The onset of puberty may be delayed or even absent. Affected individuals are usually under the 25th percentile in height, although their body weight is in the normal range.

Diagnosis

Diagnosis is usually made based on the observation of multiple lentigines and the presence of two or more of the other symptoms that form the LEOPARD acronym. Because there are so few documented cases of the multiple lentigines, it is often hard to determine if other diseases are actually part of the syndrome. A family history can be helpful in the diagnosis since the syndrome has dominant inheritance. As some genetic contributors of the syndrome are known, in some cases DNA testing can be used to confirm multiple lentigines in some patients. However, there is no readily available medical test that can definitively confirm the diagnosis of multiple lentigines syndrome.

Treatment and management

Treatment is directed toward the specific conditions of the individual. For example, heart conditions can be managed with the use of a pacemaker and appropriate medications, as well as regular medical monitoring. Hearing loss may be improved with the use of hearing aids.

Genetic counseling is recommended when there is a family history of freckle-like spotting of the skin and heart defects, as these suggest the possibility of inherited multiple lentigines syndrome.

Prognosis

The prognosis for people with multiple lentigines syndrome is good provided that the appropriate care for any associated medical conditions is available. Due to the multiple symptoms, it is suggested that a cardiologist, endocrinologist, dermatologist, and other appropriate specialists routinely see patients as symptoms present. Treatment generally focuses on palliative care of symptoms associated with the syndrome.

As the syndrome is passed on to offspring in a dominant inheritance pattern, those with the multiple lentigines who are reproductively healthy should seek genetic counseling to better understand the chances of passing it along to their children. In most cases of autosomal dominant diseases there is a 50% chance that children of affected individuals will inherit the disease.

Multiple sclerosis

Definition

Multiple sclerosis (MS) is a chronic, degenerative disorder affecting the central nervous system (CNS), which is made up of the brain, spinal cord, and optic nerves. A fatty tissue called myelin coats and protects the nerve fibers in the CNS. Myelin may be damaged or destroyed in the CNS, either by inflammation, stroke, immune disorders, metabolic disorders or nutritional deficiencies. When this occurs, scar tissue or sclerosis may form in multiple areas of the nerve fibers. As a result, the ability of the nerves to conduct electrical impulses from the brain to the rest of the body is impaired, and a wide variety of symptoms may appear.

Description

The exact cause of multiple sclerosis is not known, but researchers believe that it is caused by an inflammatory response directed at the cells of the nervous system. The reasons for this abnormal autoimmune response are uncertain, but most scientists agree that several triggers are involved, including genetics, gender, and the environment (e.g., viruses, trauma, and heavy metals).

Evidence suggests that genes associated with MS are not abnormal, but include some variations that may or may not occur in the general population. In certain combinations, however, these normal genes appear to predispose some people to develop MS after exposure to unidentified environmental factors. People with close relatives who have MS are more susceptible to

developing the disease, but there is no evidence to suggest that MS is inherited directly.

The course of the disease is unpredictable. Although MS affects each person differently, the disease generally occurs in one of four patterns, which are sometimes referred to as chronic progressive MS. The four forms of MS are relapsing-remitting, primary-progressive, secondary-progressive, and progressive-relapsing. Each of these forms may also be mild, moderate, or severe.

At initial diagnosis, the most common form of MS is relapsing-remitting, occurring in approximately 85% of those with the disease. Individuals with this form of MS experience clearly defined flare-ups (also called relapses, attacks, or exacerbations). There are episodes of acute worsening neurologic function, followed by partial or complete periods of recovery (remission) that are free of disease progression.

The primary-progressive form of MS is relatively rare, occurring in approximately 10% of patients. People with this type of MS experience a slow but nearly continuous worsening of their disease from the time of disease onset, and have no clear relapses or remissions. There are, however, variations in rates of progression over time, occasional plateaus, and temporary minor improvements.

About 50% of people with relapsing-remitting MS develop secondary-progressive MS within ten years of their initial diagnosis and before the introduction of disease-modifying drugs. Long-term data are not yet available to demonstrate if this form of MS is significantly delayed by treatment. People with secondary-progressive MS experience an initial period of relapsing-remitting disease followed by a steady progression of

Illustration showing a normal nerve fiber (left) and one affected by multiple sclerosis. (BlueRingMedia/Shutterstock)

disease course that may or may not be accompanied by occasional flare-ups, minor remissions, or plateaus.

The progressive-relapsing form of MS is relatively rare, occurring in approximately 5% of patients. People with this form of MS experience a consistent progression of disease from the onset but also have clear acute relapses, with or without recovery. As opposed to relapsing-remitting MS, the disease continues to progress between periods of relapse.

Genetic profile

Results from studies indicate that genes not only influence who is at risk for MS but also affect the clinical features of the disease, such as age of symptom onset, severity, progression, and response to drugs. In addition, there is some evidence to suggest that the different forms of MS have different underlying genetic causes. In addition to genes, other components such as exposure to viruses or environmental factors play a part in causing MS. For this reason, researchers believe that MS is not inherited directly even though genetic factors determine who is susceptible to the unknown outside trigger.

Epidemiologic studies have determined that the risk of developing MS increases several-fold if a close family member, including a first-, second-, or third-degree relative, has the disease. Studies in twins have demonstrated that a monozygotic, or identical twin, with a sibling with MS has a higher risk (estimated at 25%–30%) of developing the disease than a dizygotic, or fraternal twin (estimated at 2%–5%). Thus, a significant genetic component is involved in transmitting the susceptibility to the disease in families even if the disease is not directly inherited.

Genetically, MS is a complex disease that is not strictly dominant, recessive, or sex-linked. Discovering the genes involved in MS requires careful scanning of the entire genome (the entire genetic composition of an organism) of patients and their relatives to identify small chromosomal regions linked to the disease. Once they are discovered these genomic segments are examined in detail to determine the specific locus (location in the genome) and characteristics of the MS-associated genes.

Studies have identified approximately 60 genomic regions that may be involved in MS with 13 common regions harboring disease susceptibility, supporting the view that multiple genes are involved in this disorder. Seven of those have been confirmed with results from teams in Canada, Finland, and England that generated the first MS genetic map. These studies have sparked a global effort to search for the cause of MS susceptibility and a second-generation genome screen is near completion. Further work is needed to identify the complete list

MRI of a normal brain (left) and one with multiple sclerosis (right). The affected brain shows hyperintense lesions (yellow areas) in the periventricular white matter. (Jessica Wilson/Science Source)

of MS loci (locations) and to map the complete set of MS-associated genes.

Thus far, the HLA-DR2 haplotype (a set of closely linked alleles, or alternative forms of genes) within the major histocompatibility complex (MHC) on the short arm of chromosome 6 has the strongest genetic effect identified in MS. This haplotype has consistently demonstrated both linkage and association in family and case-control studies.

Chromosome 19q13 has been under evaluation since 1993, when the first description of positive linkage was established. Genomic screens have shown some evidence for linkage to this region, which has been identified as the second most significant region after MHC. The effect of this locus is rather modest and is estimated to account for only 4%–6% of the overall genetic component in MS. Because MS is a complex disease the data are not entirely consistent and not all studies have shown evidence of linkage.

Demographics

Multiple sclerosis is one of the most common diseases affecting the CNS. It is estimated that about 300,000 people in North America and more than 2.5 million people worldwide are affected. Peak onset occurs between the ages of 20 and 30. Almost 70% of individuals experience symptoms between the ages of 21 and 40. Although MS rarely occurs in those younger than 10 or older than 60, some cases have been reported. In addition, the disease is two to three times more common in women than men.

Although the reasons for the differences in susceptibility are not known, Caucasians are more than twice as likely as other races to develop MS. The disease is five times more common in temperate climates, such as the northern United States, Canada, and Europe, than in tropical climates. Native Americans in North America, however, rarely develop the disease. Multiple sclerosis is uncommon in Japan, China, and South America, and is

KEY TERMS

Antibodies—Proteins that are manufactured by the immune system and attack foreign substances known as antigens.

Cerebrospinal fluid (CSF)—Colorless liquid circulating through the brain and spinal cord.

Evoked response tests—Tests that measure the speed of brain connections.

Magnetic resonance imaging (MRI)—A procedure that produces images of various portions of the body using high frequency radio waves within a strong magnetic field.

Myelin—A substance rich in protein and fatty substances that forms layers around nerve fibers and acts as insulation to help transmit electrochemical messages between the brain and the rest of the body.

Poser criteria—Criteria proposed in 1983 as an update to the Schumacher criteria for diagnosing MS; developed to aid neurologists in determining the existence of lesions and other para-clinical evidence of MS.

nearly unknown among the indigenous people of equatorial Africa and the native Inuit of Alaska.

Signs and symptoms

Multiple sclerosis symptoms often progress gradually and vary in intensity and predictability because different areas of myelin are attacked in each person. Each attack produces different symptoms and new areas of the nervous system are affected. There is usually an increasing progression of symptoms, with episodes lasting days, weeks, or months, alternating with disease-free periods of remission. The disease may progress, however, without any periods of remission.

Early symptoms of MS may include the following:

- numbness and/or paresthesias (tingling) in the arms or legs
- mono- or paraparesis (partial paralysis affecting one or both of the lower limbs)
- double or blurred vision
- optic neuritis (nerve inflammation)
- ataxia (lack of muscle coordination)
- bowel- or bladder-control problems

Later symptoms of MS may include the following:

- more prominent upper motor neuron signs, such as increased spasticity (stiff or awkward movements), and increasing para- or quadriparesis
- vertigo (sensation of self or objects moving or spinning)
- lack of coordination (loss of balance) and other cerebellar problems
- depression
- emotional instability
- difficulty walking or gait abnormalities
- dysarthria (impaired speech)
- fatigue
- pain

Diagnosis

Because there is no definitive test that can identify or rule out MS, and the symptoms of MS mimic a number of other diseases, a combination of tests or procedures is required to diagnose the disease. Moreover, for some people (about 10%–15%) a definitive diagnosis is not possible even after thorough testing. In most cases with time and follow-up clinical examinations in which the condition is monitored closely, diagnosis is possible.

Diagnostic evaluation begins with a complete medical history, which assesses overall health status including an evaluation of symptoms and time of onset. Physical examination includes an evaluation of nervous system functioning by testing of reflexes, balance, coordination, and vision, as well as checking for areas of numbness or weakness.

Diagnostic testing may include:

- Magnetic resonance imaging (MRI): This provides a detailed view of the brain.
- Evoked potential tests: These measure how quickly and accurately the nervous system responds to certain stimulation; the most common of these tests include the visual evoked response test, the brainstem auditory evoked response test, and the sensory evoked response test.
- Lumbar puncture: A sample of cerebrospinal fluid (CSF) is taken from the lumbar area of the spine.
- Electrophoresis: The CSF is analyzed in a laboratory procedure used to evaluate protein levels in the CSF.

The following standard criteria, called the Poser criteria, are often used in diagnosing MS:

- Clinically definite MS is diagnosed with two attacks and clinical evidence of two separate lesions; two attacks, clinical evidence of one lesion, and para-clinical (beyond clinical) evidence of another lesion.

- Laboratory-supported definite MS is diagnosed with two attacks, either clinical or para-clinical evidence of one lesion, and CSF immunologic abnormalities; one attack, clinical evidence of two separate lesions, and CSF abnormalities; one attack, clinical evidence of one lesion and para-clinical evidence of another separate lesion, and CSF abnormalities.
- Clinically probable MS is diagnosed with two attacks and clinical evidence of one lesion; one attack and clinical evidence of two separate lesions; one attack, clinical evidence of one lesion, and para-clinical evidence of another separate lesion.
- Laboratory-supported probable MS is diagnosed with two attacks and CSF abnormalities.

Treatment and management

There is no cure for MS. Nevertheless, there are numerous drug and nondrug therapies available to manage and treat the symptoms of the disease. It is standard practice to wait until a person has experienced two or more MS attacks before initiating drug treatment. Studies indicate that initiating treatment in the early stages of the disease may lessen damage to the CNS and potentially slow disease progression. The type of treatment a patient receives is based on a wide variety of factors, including the course and severity of disease.

The U.S. Food and Drug Administration (FDA) have approved six disease-modifying drugs for use in people with MS. The drugs approved for relapsing-remitting MS include interferon beta-1a (Avonex, Rebif), interferon beta-1b (Betaseron), and glatiramer acetate (Copaxone).

These drugs, which are injected either under the skin or into the muscle, reduce the number and severity of attacks and some may slow the onset of disability. Interferons are naturally occurring proteins that fight invading viruses and although the mechanism of action of these drugs is not fully understood in MS, the drugs appear to protect the CNS from the body's attack of its own immune system. Glatiramer acetate is a synthetic compound made from substances found in myelin, and is thought to help alter the body's immune system.

The most commonly used MS drugs that have potentially serious adverse side effects include:

- Natalizumab (Tysabri, formerly known as Antegren), which was voluntarily suspended from marketing by the FDA as of February 28, 2005. This drug was approved for the treatment of relapsing forms of MS and was administered by infusion every four weeks. It is a monoclonal antibody that prevents certain white blood cells from moving into the CNS, thus decreasing inflammation and potentially allowing the body to repair

QUESTIONS TO ASK YOUR DOCTOR

- Please describe the bodily changes that take place as a result of MS.
- Why is MS considered to be a genetic disorder?
- If I have relatives with MS, is there a risk of my developing the disease?
- How is MS likely to affect my quality of life?

the damaged myelin. Although generally well tolerated, the drug was implicated in three cases of progressive multifocal leukoencephalopathy, a usually fatal brain wasting disease, among patients in long-term clinical trials. In March 2006 the FDA reevaluated Tysabri, and on June 5, 2006 the FDA approved the marketing of Tysabri under a special restricted distribution program; patients must talk to their doctor, understand the risks and benefits of Tysabri, and agree to all of the instructions in the TOUCH Prescribing Program.

- Mitoxantrone (Novantrone) is approved in the treatment of secondary-progressive, progressive-relapsing, and worsening relapsing-remitting MS. The drug has been shown to decrease relapses and slow the progression of disability. Mitoxantrone is administered intravenously and is thought to work by suppressing the immune system. Mitoxantrone has many potentially serious side effects, some of which are heart-related.
- Steroids were the gold standard of treatment for patients with MS until the discovery of the disease-modifying drugs. Although steroids are still prescribed and administered intravenously, primarily to reduce inflammation and manage acute attacks, they produce serious adverse side effects and most often are used for short periods of time. The most commonly prescribed steroids include dexamethasone (Decadron), methylprednisone (Solu-Medrol), and prednisone (Deltasone).
- Copolymer 1 is being investigated in clinical trials and may decrease disease activity. Other drugs are also used to treat the symptoms of the disease, such as fatigue, bladder control problems, and pain.

A nondrug treatment option is plasmapheresis (plasma separation or plasma exchange). This is a procedure in which the patient's blood is drawn and the plasma (liquid portion) is replaced with other fluids; an anticoagulating agent (anticoagulant) is given intravenously during the procedure. Plasma contains antibodies, and thus, this type of therapy removes antibodies that may attack myelin. The plasma-free blood is then returned to the patient.

by transfusion. This procedure, which is used to treat other autoimmune diseases, such as myasthenia gravis, Lambert-Eaton syndrome, and Guillain-Barré syndrome, has had mixed results in patients with primary- and secondary-progressive forms of MS.

Complementary and alternative therapies include vitamin D and antioxidant vitamin supplementation, as well as diets low in saturated fat and high in omega-3 fatty acids. The efficacy of these treatments has not been determined.

New treatment options include immunotherapy, in which drugs and other procedures are used to suppress the immune system; and manipulating the immune system by destroying or damaging cells that attack myelin.

Prognosis

Although the average lifespan of those diagnosed with MS is difficult to estimate because the disease pattern and severity vary among individuals, the estimate often given is 25–35 years after diagnosis.

For all MS patients, the chance of walking without assistance in 15 years following disease onset is 50%. About half of all patients require assistance in walking or will be wheelchair bound, while the other 50% of patients will be able to walk without assistance.

Some of the most common causes of death among patients with MS are related to secondary complications associated with immobility, urinary tract infections, swallowing, or breathing. Although the rate of suicide among those with MS is approximately 7.5 times higher than in the general population, the suicide rate does not correlate with disability.

Factors that tend to influence a favorable prognosis include the following:

- being female
- low relapse rate
- complete recovery from first attack
- symptoms primarily sensory in nature
- younger age of onset
- low disability at two to five years from disease onset
- later cerebellar involvement
- involvement of only one CNS component at the time of onset

Muscular dystrophy

Definition

Muscular dystrophy is the name for a group of inherited disorders in which strength and muscle bulk gradually decline. Nine types of muscular dystrophies are generally recognized.

Description

The muscular dystrophies include the following:

- Duchenne muscular dystrophy (DMD): DMD affects young boys, causing progressive muscle weakness,

Illustration showing the musculature of two humans. The one on the left is normal, while the other has muscular dystrophy. (Gale)

usually beginning in the legs. It is a severe form of muscular dystrophy. DMD occurs in about 1 in 3,500 male births, and affects approximately 8,000 boys and young men in the United States. A milder form occurs in a very small number of female carriers.

- Becker muscular dystrophy (BMD): BMD affects older boys and young men, following a milder course than DMD. It occurs in about 1 in 30,000 male births.
- Emery-Dreifuss muscular dystrophy (EDMD): EDMD affects both males and females because it can be inherited as an autosomal dominant or recessive disorder. Symptoms include contractures and weakness in the calves, weakness in the shoulders and upper arms,

and problems in the way electrical impulses travel through the heart to make it beat (heart conduction defects). Fewer than 300 cases of EDMD have been reported in the medical literature.

- Limb-girdle muscular dystrophy (LGMD): LGMD begins in late childhood to early adulthood and affects both men and women, causing weakness in the muscles around the hips and shoulders, and weakness in the limbs. It is the most variable of the muscular dystrophies, and there are several different forms of the condition now recognized. Many people with suspected LGMD have probably been misdiagnosed in the past, and therefore, the prevalence of the condition is difficult to

estimate. The highest prevalence of LGMD is in a small mountainous Basque province in northern Spain, where the condition affects 69 persons per million.

- **Facioscapulohumeral muscular dystrophy (FSH):** FSH, also known as Landouzy-Dejerine condition, begins in late childhood to early adulthood and affects both men and women, causing weakness in the muscles of the face, shoulders, and upper arms. The hips and legs may also be affected. FSH occurs in about 1 out of every 20,000 people, and affects approximately 13,000 people in the United States.
- **Myotonic dystrophy:** Also known as Steinert's disease, it affects both men and women, causing generalized weakness first seen in the face, feet, and hands. It is accompanied by the inability to relax the affected muscles (myotonia). Symptoms may begin from birth through adulthood. It is the most common form of muscular dystrophy, affecting more than 30,000 people in the United States.
- **Oculopharyngeal muscular dystrophy (OPMD):** OPMD affects adults of both sexes, causing weakness in the eye muscles and throat. It is most common among French-Canadian families in Quebec, and in Spanish-American families in the Southwestern United States.
- **Distal muscular dystrophy (DD):** DD is a group of rare muscle diseases that have weakness and wasting of the distal (farthest from the center) muscles of the forearms, hands, lower legs, and feet in common. In general, the DDs are less severe, progress more slowly, and involve fewer muscles than the other dystrophies. DD usually begins in middle age or later, causing weakness in the muscles of the feet and hands. It is most common in Sweden, and rare in other parts of the world.
- **Congenital muscular dystrophy (CMD):** CMD is a rare group of muscular dystrophies that have in common the presence of muscle weakness at birth (congenital) and abnormal muscle biopsies. CMD results in generalized weakness, and usually progresses slowly. A subtype, called Fukuyama CMD, also involves intellectual disability and is more common in Japan.

Genetic profile

The muscular dystrophies are caused by alterations in genes in an autosomal recessive pattern of inheritance. Some forms of LGMD and DD exhibit this pattern of inheritance, as does CMD. A person with only one altered copy, called a carrier, will not have the condition, but may pass the altered gene on to his children. When two carriers have children, the chances of having a child with the condition are one in four for each pregnancy.

Other conditions occur when only one altered gene copy is present. Such conditions are called autosomal

dominant conditions. DM, FSH, and OPMD exhibit this pattern of inheritance, as do some forms of DD and LGMD. When a person affected by the condition has a child with someone not affected, the chances of having an affected child are one in two.

Because of chromosomal differences between the sexes, some genes are not present in two copies. The chromosomes that determine whether a person is male or female are called the X and Y chromosomes. A person with two X chromosomes is female, while a person with one X and one Y is male. While the X chromosome carries many genes, the Y chromosome carries almost none. Therefore, a male has only one copy of each gene on the X chromosome, and if it is altered, he will have the condition that alteration causes. Such conditions are said to be X-linked. X-linked conditions include DMD, BMD, and EDMD. Women are not usually affected by X-linked conditions, since they will likely have one unaltered copy between the two chromosomes. Some female carriers of DMD have a mild form of the condition, probably because their one unaltered gene copy is shut down in some of their cells.

Female carriers of X-linked conditions have a one in two chance of passing the altered gene on to each child born. Daughters who inherit the altered gene will be carriers. A son born without the altered gene will be free of the condition and cannot pass it on to his children. A son born with the altered gene will have the condition. He will pass the altered gene on to each of his daughters, who will then be carriers, but to none of his sons (because they inherit his Y chromosome).

Not all genetic alterations are inherited. As many as one third of the cases of DMD are due to *de novo* mutations during egg formation. New mutations are less common in other forms of muscular dystrophy.

Several of the muscular dystrophies, including DMD, BMD, CMD, and most forms of LGMD, are due to alterations in the genes for a complex of muscle proteins. This complex spans the muscle cell membrane (a thin sheath that surrounds each muscle cell) to unite a fibrous network on the interior of the cell with a fibrous network on the outside. Theory holds that by linking these two networks, the complex acts as a shock absorber, redistributing and evening out the forces generated by contraction of the muscle, thereby preventing rupture of the muscle membrane. Alterations in the proteins of the complex lead to deterioration of the muscle during normal contraction and relaxation cycles. Symptoms of these conditions set in as the muscle gradually exhausts its ability to repair itself.

Both DMD and BMD are caused by alterations in the gene for the protein called dystrophin. The alteration

leading to DMD prevents the formation of any dystrophin, while that of BMD allows some protein to be made, accounting for the differences in severity and age of onset between the two conditions. Differences among the other muscular dystrophies in terms of the muscles involved and the ages of onset are less easily explained.

A number of genes have been found to cause LGMD. A majority of the more severe autosomal recessive types of LGMD with childhood-onset are caused by alterations in the genes responsible for making proteins called sarcoglycans. The sarcoglycans are a complex of proteins that are normally located in the muscle cell membrane along with dystrophin. Loss of these proteins causes the muscle cell membrane to lose some of its shock-absorber qualities. The genes responsible include *LGMD2D* on chromosome 17, which codes for the alpha-sarcoglycan protein; *LGMD2E* on chromosome 4, which codes for the beta-sarcoglycan protein; *LGMD2C* on chromosome 13, which codes for the gamma-sarcoglycan protein; and *LGMD2F* on chromosome 5, which codes for the delta-sarcoglycan protein. Some cases of autosomal recessive LGMD are caused by an alteration in a gene, *LGMD2A*, on chromosome 15, which codes for a muscle enzyme, calpain 3. The relationship between this alteration and the symptoms of the condition is unclear. Alterations in a gene called *LGMD2B* on chromosome 2 that codes for the dysferlin protein are also responsible for a minority of autosomal recessive LGMD cases. The exact role of dysferlin is not known. Finally, alterations in the *LGMD2G* gene on chromosome 17 that codes for a protein, telethonin, are responsible for autosomal recessive LGMD in two reported families. The exact role of telethonin is not known. Some families with autosomal recessive LGMD are not accounted for by alterations in any of the mentioned genes, indicating that there are as yet undiscovered genes that can cause LGMD. The autosomal dominant LGMD genes have mostly been described in single families. These types of LGMD are considered quite rare.

The genes causing these types of LGMD, their chromosomal location, and the proteins they code for (when known) are listed:

- *LGMD1A* (chromosome 5): myotilin
- *LGMD1B* (chromosome 1): laminin
- *LGMD1C* (chromosome 3): caveolin
- *LGMD1D* (chromosome 6)
- *LGMD1E* (chromosome 7)
- *COL6A1* (chromosome 21): collagen VI alpha 1
- *COL6A2* (chromosome 21): collagen VI alpha 2
- *COL6A3* (chromosome 2): collagen VI alpha 3

The causes of the other muscular dystrophies are not as well understood:

- EDMD is due to an alteration in the gene for a protein called emerin, which is found in the membrane of the nucleus, but whose exact function is unknown.
- Myotonic dystrophy is caused by alterations in a gene on chromosome 19 for an enzyme called myotonin protein kinase that may control the flow of charged particles within muscle cells. This gene alteration is called a triple repeat, meaning it contains extra triplets of DNA code. It is possible that this alteration affects nearby genes as well, and that the widespread symptoms of myotonic dystrophy are due to a range of genetic disruptions.
- The gene for OPMD appears to also be altered with a triple repeat. The function of the affected protein may involve translation of genetic messages in the nucleus.
- The gene(s) for FSH is located on the long arm of chromosome 4 at gene location 4q35. Nearly all cases of FSH are associated with a deletion (missing piece) of genetic material in this region. Researchers are investigating the molecular connection of this deletion and FSH. It is not yet certain whether the deleted material contains an active gene or changes the regulation or activity of a nearby FSH gene. A small number of FSH cases are not linked to chromosome 4. Their linkage to any other chromosome or genetic feature is under investigation.
- The gene(s) responsible for DD have not yet been found.
- About 50% of individuals with CMD have their condition as a result of deficiency in a protein called merosin, which is made by a gene called laminin. The merosin protein usually lies outside muscle cells and links them to the surrounding tissue. When merosin is not produced, the muscle fibers degenerate soon after birth. A second gene called integrin is responsible for CMD in a few individuals but alterations in this gene are a rare cause of CMD. The gene responsible for Fukuyama CMD is *FCMD* and it is responsible for making a protein called fukutin whose function is not clear.

Demographics

Muscular dystrophy in all its varying forms occurs worldwide, affecting all races and ages. The disease incidence varies, as some forms are more common than others. The most common form in children, Duchenne muscular dystrophy, affects approximately 1 in every 3,500 to 6,000 male births each year in the United States. Some types of MD are more prevalent in certain countries and regions of the world. Several versions of the disorder are familial; however, Duchenne cases often have no prior family history. This is likely due to the large size

of the dystrophin gene that is implicated in the disorder, making it a more significant target for mutations.

Signs and symptoms

All of the muscular dystrophies are marked by muscle weakness as the major symptom. The distribution of symptoms, age of onset, and progression differ significantly. Pain is sometimes a symptom of each, usually due to the effects of weakness on joint position.

DUCHENNE MUSCULAR DYSTROPHY (DMD). A boy with Duchenne muscular dystrophy usually begins to show symptoms as a pre-schooler. The legs are affected first, making walking difficult and causing balance problems. Most patients walk three to six months later than expected and have difficulty running. Later on, a boy with DMD will push his hands against his knees to rise to a standing position, to compensate for leg weakness. About the same time, his calves will begin to enlarge, though with fibrous tissue rather than with muscle, and feel firm and rubbery; this condition gives DMD one of its alternate names, pseudohypertrophic muscular dystrophy. He will widen his stance to maintain balance, and walk with a waddling gait to advance his weakened legs. Contractures (permanent muscle tightening) usually begin by age five or six, most severely in the calf muscles. This pulls the foot down and back, forcing the boy to walk on tip-toes, and further decreases balance. Climbing stairs and rising unaided may become impossible by age nine or ten, and most boys use a wheelchair for mobility by the age of 12. Weakening of the trunk muscles around this age often leads to scoliosis (a side-to-side spine curvature) and kyphosis (a front-to-back curvature).

The most serious weakness of DMD is weakness of the diaphragm, the sheet of muscles at the top of the abdomen that perform the main work of breathing and coughing. Diaphragm weakness leads to reduced energy and stamina, and increased lung infection because of the inability to cough effectively. Young men with DMD often live into their 20s and beyond, provided they have mechanical ventilation assistance and good respiratory hygiene.

Among males with DMD, the incidence of cardiomyopathy (weakness of the heart muscle) increases steadily in teenage years. Almost all patients have cardiomyopathy after 18 years of age. It has also been shown that carrier females are at increased risk for cardiomyopathy and should also be screened.

About one third of males with DMD experience specific learning disabilities, including difficulty learning by ear rather than by sight and difficulty paying attention to long lists of instructions. Individualized educational programs usually compensate well for these disabilities.

BECKER MUSCULAR DYSTROPHY (BMD). The symptoms of BMD usually appear in late childhood to early adulthood. Though the progression of symptoms may parallel that of DMD, the symptoms are usually milder and the course more variable. The same pattern of leg weakness, unsteadiness, and contractures occurs later for the young man with BMD, often allowing independent walking into the 20s or early 30s. Scoliosis may occur, but is usually milder and progresses more slowly. Cardiomyopathy occurs more commonly in BMD. Problems may include irregular heartbeats (arrhythmias) and congestive heart failure. Symptoms may include fatigue, shortness of breath, chest pain, and dizziness. Respiratory weakness also occurs, and may lead to the need for mechanical ventilation.

EMERY-DREIFUSS MUSCULAR DYSTROPHY (EDMD). This type of muscular dystrophy usually begins in early childhood, often with contractures preceding muscle weakness. Weakness affects the shoulder and upper arm initially, along with the calf muscles, leading to foot-drop. Most men with EDMD survive into middle age, although an abnormality in the heart's rhythm (heart block) may be fatal if not treated with a pacemaker.

LING-GIRDLE MUSCULAR DYSTROPHY (LGMD). While there are several genes that cause the various types of LGMD, two major clinical forms of LGMD are usually recognized. A severe childhood form is similar in appearance to DMD, but is inherited as an autosomal recessive trait. Symptoms of adult-onset LGMD usually appear in a person's teens or 20s, and are marked by progressive weakness and wasting of the muscles closest to the trunk. Contractures may occur, and the ability to walk is usually lost about 20 years after onset. Some people with LGMD develop respiratory weakness that requires use of a ventilator. Lifespan may be somewhat shortened. Autosomal dominant forms usually occur later in life and progress relatively slowly.

FACIOSCAPULOHUMERAL MUSCULAR DYSTROPHY (FSH). FSH varies in its severity and age of onset, even among members of the same family. Symptoms most commonly begin in the teens or early 20s, though infant or childhood onset is possible. Symptoms tend to be more severe in those with earlier onset. The condition is named for the regions of the body most severely affected by the condition: muscles of the face (facio-), shoulders (scapulo-), and upper arms (humeral). Hips and legs may be affected as well. Children with FSH may develop partial or complete deafness.

The first symptom noticed is often difficulty lifting objects above the shoulders. The weakness may be greater on one side than the other. Shoulder weakness also causes the shoulder blades to jut backward, called scapular winging. Muscles in the upper arm often lose

bulk sooner than those of the forearm, giving a “Popeye” appearance to the arms. Facial weakness may lead to loss of facial expression, difficulty closing the eyes completely, and inability to drink through a straw, blow up a balloon, or whistle. A person with FSH may not be able to wrinkle their forehead. Contracture of the calf muscles may cause foot-drop, leading to frequent tripping over curbs or rough spots. People with earlier onset often require a wheelchair for mobility, while those with later onset rarely do.

MYOTONIC DYSTROPHY. Symptoms of myotonic dystrophy include facial weakness and a slack jaw, drooping eyelids (ptosis), and muscle wasting in the forearms and calves. A person with myotonic dystrophy has difficulty relaxing his grasp, especially if the object is cold. Myotonic dystrophy affects heart muscle, causing arrhythmias and heart block, and the muscles of the digestive system, leading to motility disorders and constipation. Other body systems are affected as well; myotonic dystrophy may cause cataracts, retinal degeneration, mental deficiency, frontal balding, skin disorders, testicular atrophy, sleep apnea, and insulin resistance. An increased need or desire for sleep is common, as is diminished motivation. The condition is extremely variable; some individuals show profound weakness as a newborn (congenital myotonic dystrophy), others show intellectual disability in childhood, and many show characteristic facial features and muscle wasting in adulthood, while the most mildly affected individuals show only cataracts in middle age with no other symptoms. Individuals with a severe form of myotonic dystrophy typically have severe disabilities within 20 years of onset, although most do not require a wheelchair even late in life.

OCULOPHARYNGEAL MUSCULAR DYSTROPHY (OPMD). OPMD usually begins in a person’s 30s or 40s, with weakness in the muscles controlling the eyes and throat. Symptoms include drooping eyelids and difficulty swallowing (dysphagia). Weakness progresses to other muscles of the face, neck, and occasionally the upper limbs. Swallowing difficulty may cause aspiration, or the introduction of food or saliva into the airways. Pneumonia may follow.

DISTAL MUSCULAR DYSTROPHY (DD). DD usually begins in the 20s or 30s, with weakness in the hands, forearms, and lower legs. Difficulty with fine movements such as typing or fastening buttons may be the first symptom. Symptoms progress slowly, and the condition usually does not affect lifespan.

CONGENITAL MUSCULAR DYSTROPHY (CMD). CMD is marked by severe muscle weakness from birth, with infants displaying floppiness, very poor muscle tone, and trouble moving their limbs or head against gravity.

Mental function is normal but some are never able to walk. They may live into young adulthood or beyond. In contrast, children with Fukuyama CMD are rarely able to walk, and have severe intellectual disability. Most children with this type of CMD die in childhood.

Diagnosis

The diagnosis of muscular dystrophy involves a careful medical history and a thorough physical exam to determine the distribution of symptoms and to rule out other causes. Family history may give important clues, since all the muscular dystrophies are genetic conditions (though no family history will be evident in the event of new mutations; in autosomal recessive inheritance, the family history may also be negative).

Lab tests may include:

- **Blood level of the muscle enzyme creatine kinase (CK):** CK level increases due to muscle damage, and may be seen in some conditions even before symptoms appear.
- **Muscle biopsy:** A small piece of muscle tissue is removed for microscopic examination. Changes in the structure of muscle cells and presence of fibrous tissue or other aberrant structures are characteristic of different forms of muscular dystrophy. The muscle tissue can also be stained to detect the presence or absence of particular proteins, including dystrophin.
- **Electromyogram (EMG):** This electrical test is used to examine the response of the muscles to stimulation. Decreased response is seen in muscular dystrophy. Other characteristic changes are seen in DM.
- **Genetic tests:** Several of the muscular dystrophies can be positively identified by testing for the presence of the altered gene involved. Accurate genetic tests are available for DMD, BMD, DM, several forms of LGMD, and EDMD. Genetic testing for some of these conditions in future pregnancies of an affected individual or parents of an affected individual can be done before birth through amniocentesis or chorionic villus sampling.
- **Other specific tests as necessary:** For EDMD, DMD, and BMD, for example, an electrocardiogram may be needed to test heart function, and hearing tests are performed for children with FSH.

For most forms of muscular dystrophy, accurate diagnosis is not difficult when done by someone familiar with the range of conditions. There are some exceptions, even with a muscle biopsy; it may be difficult to distinguish between FSH and another muscle condition, polymyositis. Childhood-onset LGMD is often mistaken for the much more common DMD, especially when it occurs in boys. BMD with an early onset appears very similar to

DMD, and a genetic test may be needed to accurately distinguish them. The muscular dystrophies may be confused with conditions involving the motor neurons, such as spinal muscular atrophy; conditions of the neuromuscular junction, such as myasthenia gravis; and other muscle conditions, as all involve generalized weakness of varying distribution.

Prenatal diagnosis (testing of the baby while in the womb) can be done for those types of muscular dystrophy where the specific disease-causing gene alteration has been identified in a previously affected family member. Prenatal diagnosis can be done utilizing DNA extracted from tissue obtained by chorionic villus sampling or amniocentesis.

Treatment and management

Drugs

There are no cures for any of the muscular dystrophies. Prednisone, a corticosteroid, has been shown to delay the progression of DMD somewhat, for reasons that are still unclear. Some have reported improvement in strength and function in patients treated with a single dose. Improvement begins within ten days and plateaus after three months. Long-term benefit has not been demonstrated. Prednisone is also prescribed for BMD, though no controlled studies have tested its benefit. A study is under way in the use of gentamicin, an antibiotic that may slow down the symptoms of DMD in a small number of cases. Treatment of muscular dystrophy is mainly directed at preventing the complications of weakness, including decreased mobility and dexterity, contractures, scoliosis, heart alterations, and respiratory insufficiency.

Physical therapy

Physical therapy, regular stretching in particular, is used to maintain the range of motion of affected muscles and to prevent or delay contractures. Braces are used as well, especially on the ankles and feet to prevent tip-toeing. Full-leg braces may be used in children with DMD to prolong the period of independent walking. Strengthening other muscle groups to compensate for weakness may be possible if the affected muscles are few and isolated, as in the earlier stages of the milder muscular dystrophies. Regular, non-strenuous exercise helps maintain general good health. Strenuous exercise is usually not recommended, since it may damage muscles further.

Surgery

When contractures become more pronounced, tenotomy surgery may be performed. In this operation, the tendon of the contracted muscle is cut, and the limb is braced in its normal resting position while the tendon

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman’s abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Autosomal dominant—A pattern of genetic inheritance where only one abnormal gene is needed to display the trait or disease.

Autosomal recessive—A pattern of genetic inheritance where two abnormal genes are needed to display the trait or disease.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted either through the mother’s vagina or abdominal wall and a sample of cells is collected from around the fetus. These cells are then tested for chromosome abnormalities or other genetic diseases.

Contracture—A tightening of muscles that prevents normal movement of the associated limb or other body part.

Dystrophin—A protein that helps muscle tissue repair itself. Both Duchenne muscular dystrophy and Becker muscular dystrophy are caused by flaws in the gene that instructs the body how to make this protein.

Myotonic dystrophy—A form of muscular dystrophy, also known as Steinert’s condition, characterized by delay in the ability to relax muscles after forceful contraction, and wasting of muscles, as well as other abnormalities.

regrows. In FSH, surgical fixation of the scapula can help compensate for shoulder weakness. For a person with OPMD, surgical lifting of the eyelids may help compensate for weakened muscular control. For a person with DM, sleep apnea may be treated surgically to maintain an open airway. Scoliosis surgery is often needed in boys with DMD, but much less often in other muscular dystrophies. Surgery is recommended at a much lower degree of curvature for DMD than for scoliosis due to other conditions, since the decline in respiratory function in DMD makes surgery at a later time dangerous. In this surgery, the vertebrae are fused together to maintain the spine in the upright position. Steel rods are inserted at the

time of operation to keep the spine rigid while the bones grow together. When any type of surgery is performed in patients with muscular dystrophy, anesthesia must be carefully selected. People with MD are susceptible to a severe reaction, known as malignant hyperthermia, when given halothane anesthetic.

Occupational therapy

The occupational therapist suggests techniques and tools to compensate for the loss of strength and dexterity. Strategies may include modifications in the home, adaptive utensils and dressing aids, compensatory movements and positioning, wheelchair accessories, or communication aids.

Nutrition

Good nutrition helps to promote general health in all the muscular dystrophies. No special diet or supplement has been shown to be of use in any of the conditions. The weakness in the throat muscles seen especially in OPMD and later DMD may necessitate the use of a gastrostomy tube, inserted in the stomach to provide nutrition directly.

Cardiac care

The arrhythmias of EDMD and BMD may be treatable with antiarrhythmia drugs. A pacemaker may be implanted if these do not provide adequate control. Heart transplants are increasingly common for men with BMD. A complete cardiac evaluation is recommended at least once in all carrier females of DMD and EDMD.

Respiratory care

People who develop weakness of the diaphragm or other ventilatory muscles may require a mechanical ventilator to continue breathing deeply enough. Air may be administered through a nasal mask or mouthpiece, or through a tracheostomy tube, which is inserted through a surgical incision through the neck and into the windpipe. Most people with muscular dystrophy do not need a tracheostomy, although some may prefer it to continual use of a mask or mouthpiece. Supplemental oxygen is not needed. Good hygiene of the lungs is critical for health and long-term survival of a person with weakened ventilatory muscles. Assisted cough techniques provide the strength needed to clear the airways of secretions; an assisted cough machine is also available and provides excellent results.

Experimental treatments

Two experimental procedures aiming to cure DMD have attracted a great deal of attention. In myoblast transfer, millions of immature muscle cells are injected into an affected muscle. The goal of the treatment is to

QUESTIONS TO ASK YOUR DOCTOR

- Why does my doctor use the term “muscular dystrophies” rather than just “muscular dystrophy”?
- Are there ways I can help my child maintain muscle function as her condition develops?
- What is the long-term prognosis for the type of muscular dystrophy my child has?
- What is the status of current research on cures for muscular dystrophy?

promote the growth of the injected cells, replacing the abnormal host cells with healthy new ones. Myoblast transfer is under investigation but remains experimental.

Gene therapy introduces unaltered copies of the altered gene into muscle cells. The goal is to allow the existing muscle cells to use the new gene to produce the protein it cannot make with its abnormal gene. Problems with gene therapy research have included immune rejection of the virus used to introduce the gene, loss of gene function after several weeks, and an inability to get the gene to enough cells to make a functional difference in the affected muscle. Researchers are preparing for the first gene therapy trial for LGMD in the United States. The goal will be to replace the missing sarcoglycan gene(s). Additionally, clinical trials have tested the use of oligonucleotide (2'OMe [PRO051] and PMO [AVI-4658]) therapy for MDM and have seen very promising improvements in the levels of dystrophin observed both with local or systemic injections. However, there are two observed obstacles to these therapies. First, effective cell penetration of the tested formulations is lacking, and second, the effect of the current formulations on the cardiac muscle is very limited. To address these issues alternate formulations have been created utilizing cell penetrating peptides (CPP)-conjugated PMO (PPMO) and seem to be promising, though these new formulas are still being investigated.

Genetic counseling

Individuals with muscular dystrophy and their families may benefit from genetic counseling for information on the condition and recurrence risks for future pregnancies.

Prognosis

The expected lifespan for a male with DMD has increased significantly. Most young men will live into their early or mid 20s. Respiratory infections become an

increasing problem as their breathing becomes weaker, and these infections are usually the cause of death.

The course of the other muscular dystrophies is more variable; expected lifespans and degrees of disability are hard to predict, but may be related to age of onset and initial symptoms. Prediction is made more difficult because, as new genes are discovered, it is becoming clear that several of the dystrophies are not uniform disorders, but rather symptom groups caused by different genes.

People with dystrophies with significant heart involvement (BMD, EDMD, myotonic dystrophy) may nonetheless have almost normal lifespans, provided that cardiac complications are monitored and treated aggressively. The respiratory involvement of BMD and LGMD similarly require careful and prompt treatment. There is no way to prevent any of the muscular dystrophies in a person who has the genes responsible for these disorders. Accurate genetic tests, including prenatal tests, are available for some of the muscular dystrophies. Results of these tests may be useful for purposes of family planning.

Mutations (on-target and off-target)

Definition

On-target mutations are intentional changes, and off-target mutations are unintentional changes in the genetic material (genome) of an organism caused by genome editing.

Description

Genome editing is a technique used by researchers to change the genetic sequence of an organism. In humans, it is done to fix errors in the sequence and treat or prevent genetic disease. In agriculture and food production, genome editing is used to improve certain traits of the plant or animal, such as disease tolerance and yield.

Often genome editing involves changes to the DNA sequence, which contains the instructions for creating proteins. A three-base sequence in the DNA contains the instructions for making a particular amino acid. Proteins are made up of one amino acid or several amino acids strung together.

An intentional change made through genome editing is called on-target mutation. Such changes are often designed to fix an error. On-target mutations in genome editing include adding a piece of DNA (insertion), removing a piece of DNA (deletion), or causing a point mutation. On-target point mutations in genome editing involve substituting one DNA base for another, or inserting or deleting one base.

Unfortunately genome editing techniques can result in unintended mutations, called off-target mutations. Off-target mutations can include point mutations, deletions, insertions, sequences switched around (inversions), and pieces moved from one area to another (translocations).

Sometimes off-target mutations are silent, meaning they do not affect the organism. Other times they disrupt a gene and result in the production of absent or abnormal proteins.

KEY TERMS

Cell—Building block that provides structure to the body and performs all the functions of the body. Cells contain genetic information and can copy themselves. The four main types of cells are: skin, nerve, muscle, and connective tissue.

Chromosome—The package of DNA found in each cell of the human body apart from the red blood cells. Humans have 22 pairs of autosomes (1 to 22) and one pair of sex chromosomes (XY). Females have two X chromosomes, and males have an X and Y. Normally, individuals inherit one chromosome of each pair from their mother and one from their father.

Deletion—Mutation where a single base pair or sequence of base pairs is missing.

DNA (deoxyribonucleic acid)—The genetic material that contains the instructions for creating proteins.

DNA base—One unit in a DNA sequence. The four DNA bases are adenine (A), cytosine (C), guanine (G), and thymine (T). The sequence of these bases is the genetic code that contains the instructions for creating proteins.

DNA sequence—The sequence of DNA bases that contains the instructions for creating proteins. A three base sequence in the DNA contains the instructions for making a particular amino acid. For example, CGC codes for the amino acid alanine. Proteins are made up of one amino acid or several amino acids strung together. The instructions for a particular protein are made up of a number of three base sequences.

Gene—A sequence of bases in a DNA sequence that contains the instructions for one protein.

Genome—The complete set of genetic instructions of an organism.

Genome editing—A technique used by researchers to change the sequence of genetic material, for example, the DNA, of an organism. It can be used to fix a pathogenic mutation that can cause disease.

Insertion—Mutation where there is an extra single base pair or sequence of base pairs.

Oncogene—A pathogenic variant (mutation) in a proto-oncogene that turns it into an oncogene which does not regulate the cell well, making it more likely to become cancerous.

On-target point mutation—The substitution of one DNA base for another or insertion or deletion of one base.

Pathogenic variant—Any change in the sequence of a genome that causes disease.

Point mutation (DNA)—Error in the DNA sequence where one DNA base is substituted for another or inserted or deleted.

Sickle cell disease—A genetic disease that causes abnormal red blood cells that cannot properly carry oxygen throughout the body.

Tissue—Matter made up of cells that have a common function. The four types of tissue are: connective, epithelial (skin), muscle, and nervous.

Tumor suppressor genes—Genes that normally help prevent cancer from developing in a cell. Variants (mutations) in tumor suppressor genes make the cell more likely to become cancerous.

Variant—Change in the sequence of DNA.

Whole genome sequencing—A way to look at the sequence of an organism's genome by looking for variants (mutations) in the whole genome.

Mutations in somatic and germline genome editing

Genome editing can be accomplished in either somatic or germline cells. Somatic genome editing involves changing the genetic sequence in a tissue or cell other than an egg or sperm cell. Somatic genome editing is often used to correct an error in the genetic sequence that results in a missing or abnormal protein. Somatic genome editing fixes that error so that a functioning protein is produced in the cells that are targeted. This procedure can be performed on cells outside the body (in vitro), which are then transferred to the patient or directly on cells in the body (in vivo).

Germline genome editing changes the genetic material in either an egg or sperm or early embryo. Germline genome editing will cause permanent changes in the individual and that individual's offspring, and can be used to prevent a genetic disease.

The risk of off-target mutation is increased with in vivo somatic genome editing in which the genome editing is done directly in the body. In this case, in vivo somatic genome editing may cause off-target mutations in a variety of cells and tissues in the body. In vitro genome editing, by contrast, will only result in off-target mutations in the specific cells that are being targeted outside the body.

In vivo genome editing is used in treatment of Hunter syndrome, in which mutations in the IDS gene cause the IDS protein not to function properly. Sugars build up in the body, which can damage organs and result in brain, heart, and lung damage, and early death. To treat this condition, a normal IDS gene is injected into patients with Hunter syndrome. The gene contains the instructions for the production of a normal IDS protein. The hope is that by inserting a normal gene into the cells enough normal protein will be produced to prevent the accumulation of sugars. Gene editing for conditions such as Hunter syndrome may be worth the risk provided that researchers thoroughly examine the target sequence and other areas of the genome that could be unintentionally targeted.

One advantage of somatic genome editing is that off-target mutations will not result in permanent changes that can affect future generations. Also the off-target mutations will not affect all the cells of the body.

Off-target mutations in germline editing, by contrast, results in permanent changes to the whole embryo, which can be passed on to future generations. One study of genome editing on embryos found that, in addition to the typical small insertions and deletions, about 16% of the embryos had large off-target mutations that would not have been detected through traditional methods for detecting DNA changes. Other studies have found an increased risk of mosaic embryos resulting from genome editing. A mosaic embryo has some cells without the genetic change and some with the genetic change. This condition can result in abnormalities in the embryo.

Methods of decreasing off-target mutations

Modern genome editing techniques involve the use of guide RNAs, which guide a genome editor to a target location on the DNA or RNA. The genome editor includes a nuclease that makes a cut in the DNA. Then either the genome editor creates the on-target mutation, or it tricks the DNA repair mechanism of the organism to make the change. If there is a sequence of DNA in another location that is similar to the target location, then the RNA guide may also guide the editor to make a change in this site, which results in an off-target mutation.

When possible, it is important to choose a target location that has a different sequence than other non-targeted locations in the DNA. For example, one study found that the number of off-target mutations decreased significantly when the target sequence had three mismatches or more to any other similar sequences in the DNA.

Newer genome editing techniques, such as base editing and prime editing, are more precise and require a cut in only one strand of the DNA. They generally result in

fewer off-target mutations than genome editing systems that rely on a double stranded break in the DNA, such as nuclease-zinc-finger nuclease (ZFN), TALEN, or CRISPR-Cas.

Before physicians perform genome editing for a particular disease, they must determine what off-target mutations are likely and how serious they might be. For example, if physicians are planning to treat a disease such as sickle cell disease by doing somatic genome editing in blood cells, then off-target mutations that make changes in a gene only found in the muscle cells will be less concerning. If they are trying to treat muscular dystrophy by somatic genome editing of muscle cells, then off-target mutations in beta-globin genes, which are not active in muscle cells, are likely acceptable.

Possible off-target mutations in genes that can cause cancer, such as tumor suppressor genes or oncogenes, should be avoided. Even if these off-target mutations only happen in a few cells, there is a high risk of cancer. That is because mutations in an oncogene or tumor suppressor gene would give these cells a growth advantage that could help them overtake the normal cells.

This problem occurred in genome editing clinical trials involving patients who had severe abnormalities in their immune system. The vector transporting the genome editing material integrated into the DNA near an oncogene and activated it in some cells. Activation of this oncogene caused the affected cells to grow out of control and resulted in leukemia. There were so few cells that had the activated oncogene that it was impossible to detect with DNA sequencing techniques that look for mutations in the whole genome (whole genome sequencing). Thus, when physicians consider potential targets for genome editing, they must select sequencing that looks at specific oncogene and tumor suppressor genes rather than relying only on whole genome sequencing.

On-target and off-target mutations in agriculture

Genome editing is used on crops and livestock to improve favorable traits such as disease resistance. It is easier to deal with off-target mutations when using genome editing on plant crops and livestock. Genome editing can be done on cells from semen and seeds. Plants or animals from the first generation after genome editing can be examined to see if there are any adverse effects on the health of the organism or the quality of the food produced. Genome editing can also be done to look for off-target mutations. Many serious off-target mutations can prevent the plant or animal from reproducing. Off-target mutations that do not cause any obvious adverse effect are usually tolerated. Many existing strains of crop

plants have mutations that resulted from early genome editing techniques using radiation or chemicals.

Myasthenia gravis

Definition

Myasthenia gravis (MG) is an autoimmune neuromuscular disease that causes muscle weakness in certain voluntary muscle groups.

Description

The name myasthenia gravis literally means "grave muscle weakness." MG affects the neuromuscular junction, interrupting the communication between nerve and muscle, and thereby causing weakness. A person with MG may have difficulty moving their eyes, walking, speaking clearly, swallowing, and even breathing, depending on the severity and distribution of weakness. Increased weakness with exertion, and improvement with rest, is a characteristic feature of MG.

In MG, the immune system attacks a receptor on the surface of muscle cells. This prevents the muscle from receiving the nerve impulses that normally make it respond. MG affects voluntary muscles, which are those muscles under conscious control responsible for movement. It does not affect heart muscle or the smooth muscle found in the digestive system and other internal organs.

A muscle is stimulated to contract when the nerve cell controlling it releases acetylcholine molecules onto its surface. The acetylcholine binds to a muscle protein called the acetylcholine receptor. This leads to rapid chemical changes in the muscle, causing contraction. Acetylcholine is then broken down by acetylcholinesterase enzyme, preventing further stimulation.

In MG, immune cells create antibodies against the acetylcholine receptor. Antibodies are proteins normally involved in fighting infection. When these antibodies attach to the receptor, they prevent it from receiving acetylcholine, decreasing the ability of the muscle to respond to stimulation.

Why the immune system creates these self-reactive autoantibodies is unknown, although there are several hypotheses:

- During fetal development, the immune system generates many B cells that can make autoantibodies, but B cells that could harm the body's own tissues are screened out and destroyed before birth. It is possible that the stage is set for MG when some of these cells escape detection.
- Genes controlling other parts of the immune system, called Major Histone Compatibility (MHC) genes, appear to influence how susceptible a person is to developing autoimmune disease.
- Infection may trigger some cases of MG. When activated, the immune system may mistake portions of the acetylcholine receptor for portions of an invading virus, though no candidate virus has yet been identified conclusively.
- About 10% of those with MG also have thymomas, or benign tumors of the thymus gland. The thymus is a principal organ of the immune system, and researchers speculate that thymic irregularities are involved in the progression of MG.

Familial inheritance of Myasthenia gravis (Gale)

Some or all of these factors (developmental, genetic, infectious, and thymic) may interact to create the autoimmune reaction.

Genetic profile

Myasthenia gravis is similar to many autoimmune diseases. It is a multifactorial, non-inherited disease with documented genetic contributing factors. Genome-wide association studies conducted in 2015 have identified three gene variants that are susceptible loci: *CTLA4* (rs231770), *HLA-DQA1* (rs9271871), and *TNFRSF11A* (rs4263037). MG is a very heterogeneous disease varying in severity of symptoms, autoantigens produced, and ages of onset. Three autoantigens have been identified to cause 90%–95% of clinical cases. The muscle acetylcholine receptor (AChR) accounts for up to 85% of diagnosed cases, and the remaining cases have been identified as autoantibodies against the muscle-specific tyrosine kinase (MuSK) and the low-density-lipoprotein-receptor-related protein 4 (LRP4). It is important to note that there are many possible epitope variations of these three targets, and that individuals may have autoantibodies to more than one epitope.

Demographics

About 36,000 people in the United States are affected by MG, roughly 14 people per 100,000. The age of onset delineates patients into two subgroups: early-onset MG (EOMG), where patients develop the disease before the age of 40, and late-onset MG (LOMG),

where patients develop the disease after 40 years of age. The two subgroups are further characterized by gender predominance, with EOMG being predominantly female (3:1) and LOMG predominantly male. Pathology of the thymus within each subgroup has been documented. EOMG is characterized by hyperplastic thymus pathology, and LOMG typically has either normal or atrophic pathology. Occasionally the disease is present in more than one person in a family.

Signs and symptoms

The earliest symptoms of MG often result from weakness of the extra-ocular muscles, which control eye movements. Symptoms involving the eye (ocular symptoms) include double vision (diplopia), especially when not gazing straight ahead, and difficulty raising the eyelids (ptosis). A person with ptosis may need to tilt his or her head back to see. Eye-related symptoms remain the only symptoms for about 15% of MG patients. Another common early symptom is difficulty chewing and swallowing, due to weakness in the bulbar muscles, which are in the mouth and throat. Choking becomes more likely, especially with food that requires extensive chewing.

Weakness usually becomes more widespread within several months of the first symptoms, reaching their maximum within a year in two-thirds of patients. Weakness may involve muscles of the arms, legs, neck, trunk, and face, and affect the ability to lift objects, walk, hold the head up, and speak.

Symptoms of MG become worse upon exertion and better with rest. Heat, including heat from the sun, hot showers, and hot drinks may increase weakness. Infection and stress may worsen symptoms. Symptoms may vary from day to day and month to month, with intervals of no weakness interspersed with a progressive decline in strength.

Myasthenic crisis is an emergency condition requiring immediate treatment. It may occur when the breathing muscles become too weak to provide adequate respiration. Symptoms include weak and shallow breathing, shortness of breath, pale or bluish skin color, and a racing heart. In patients treated with anticholinesterase agents, myasthenic crisis must be differentiated from cholinergic crisis related to overmedication.

Pregnancy worsens MG in about one third of women, has no effect in one third, and improves symptoms in another third. About 12% of infants born to women with MG have neonatal myasthenia, a temporary but potentially life-threatening condition caused by the transfer of maternal antibodies into the fetal circulation just before birth. Symptoms include weakness, poor muscle tone, feeble cry, and difficulty feeding. The infant may have difficulty breathing, requiring the use of a ventilator. Neonatal myasthenia usually clears up within a month.

Diagnosis

Myasthenia gravis is often diagnosed accurately by a careful medical history and a neuromuscular exam, but several tests are used to confirm the diagnosis. Other conditions causing worsening of bulbar and skeletal muscles must be considered, including drug-induced myasthenia,

KEY TERMS

Antibody—A protein produced by the mature B cells of the immune system that attach to invading pathogens/antigens and target them for destruction by other immune system cells.

Autoantibody—An antibody that reacts against part of the self.

Autoimmune disease—Describes a group of diseases characterized by an inflammatory immune reaction erroneously directed toward ‘self’ tissues.

Bulbar muscles—Muscles that control chewing, swallowing, and speaking.

Epitope—The specific piece of an antigen that an antibody binds to.

Neuromuscular junction—The site at which nerve impulses are transmitted to muscles.

Pyridostigmine bromide (Mestinon)—An anticholinesterase drug used in treating myasthenia gravis.

Thymus gland—An endocrine gland located in the front of the neck that houses and transports T cells, which help to fight infection.

thyroid disease, Lambert-Eaton myasthenic syndrome, botulism, and inherited muscular dystrophies.

MG causes characteristic changes in the electrical responses of muscles that may be observed with an electromyogram, which measures muscular response to

Sporadic occurrence of Myasthenia gravis in a family (Gale)

electrical stimulation. Repetitive nerve stimulation leads to reduction in the height of the measured muscle response, reflecting the muscle's tendency to become fatigued.

Blood tests may confirm the presence of the antibody to the acetylcholine receptor, though up to a quarter of MG patients will not have detectable levels. A chest x-ray or chest computed tomography scan (CT scan) may be performed to look for thymomas.

Treatment and management

While there is no cure for myasthenia gravis, there are a number of treatments that effectively control symptoms in most people. Pyridostigmine (Mestinon) is usually the first drug prescribed. Pyridostigmine blocks acetylcholinesterase, is longer-acting, taken by mouth, and well-tolerated. Loss of responsiveness and disease progression combine to eventually make pyridostigmine ineffective in tolerable doses in many patients.

Thymectomy, or removal of the thymus gland, has increasingly become standard treatment for MG. Up to 85% of people with MG improve after thymectomy, with complete remission eventually seen in about 30%. The improvement may take months or even several years to fully develop. Thymectomy is not usually recommended for children with MG, since the thymus continues to play an important immune role throughout childhood.

Immune-suppressing drugs are used to treat MG if response to pyridostigmine and thymectomy are not adequate. Drugs include corticosteroids such as prednisone, and the non-steroids azathioprine (Imuran) and cyclosporine (Sandimmune).

Plasma exchange may be performed to treat myasthenic crisis or to improve very weak patients before thymectomy. In this procedure, blood plasma is removed and replaced with purified plasma free of autoantibodies. It can produce a temporary improvement in symptoms, but is too expensive for long-term treatment. Another blood treatment, intravenous immunoglobulin therapy, is also used for myasthenic crisis. In this procedure, large quantities of purified immune proteins (immunoglobulins) are injected. For unknown reasons, this leads to symptomatic improvement in up to 85% of patients. It is also too expensive for long-term treatment.

People with weakness of the bulbar muscles may need to eat softer foods that are easier to chew and swallow. In more severe cases, it may be necessary to obtain nutrition through a feeding tube placed into the stomach (gastrostomy tube).

QUESTIONS TO ASK YOUR DOCTOR

- How do you plan to treat my myasthenia gravis syndrome?
- Are there treatment options?
- Is surgery required?
- What is the expected outcome?
- How do autoimmune diseases develop?

Some drugs should be avoided by people with MG because they interfere with normal neuromuscular function. Drugs to be avoided or used with caution include:

- Several antibiotics, including erythromycin, streptomycin, and ampicillin
- Cardiovascular drugs, including verapamil, betaxolol, and propranolol
- Drugs used in psychiatric conditions, including chlorpromazine, clozapine, and lithium

Many other drugs may exacerbate symptoms, so patients should check with the doctor who treats their MG before taking any new medications.

A Medic-Alert card or bracelet provides an important source of information to emergency providers about the special situation of a person with MG. They are available from health care providers.

Prognosis

Most people with MG can be treated successfully enough to prevent their condition from becoming debilitating. In some cases, however, symptoms may worsen even with vigorous treatment, leading to generalized weakness and disability. MG rarely causes early death except from myasthenic crisis. There is no known way to prevent myasthenia gravis. Thymectomy improves symptoms significantly in many patients, and relieves them entirely in some. Avoiding heat can help minimize symptoms.

MYH9-related disorders

Definition

MYH9-related disorders are extremely rare genetic diseases that result in impaired blood clotting function and abnormal platelet formation. Another name for *MYH9*-related disorders is autosomal dominant macrothrombocytopenia with leukocyte inclusions.

Description

MYH9-related disorders are classified as one of the inherited giant platelet disorders (IGPDs). Platelet cells are components of the blood that play a key role in blood clotting. All IGPDs are associated with bleeding disorders due to few platelets, improper platelet function, and increased platelet cell size. A subclass of IGPDs include the non-muscle myosin-heavy chain 9 (*MYH9*)-related disorders (*MYH9*-RD). Mutations in the *MYH9* gene result in several disease pathologies, including Sebastian syndrome, May-Hegglin anomaly, Epstein syndrome, and Fechtner syndrome, which are characterized by the distinct disease symptoms. People affected by *MYH9*-related disorders have mild, non-life-threatening dysfunction of the blood related to decreased blood clotting function. They may bruise easily or be prone to nosebleeds.

Genetic profile

MYH9-related disorders are inherited as an autosomal dominant trait. Autosomal means that the syndrome is not carried on a sex chromosome, while dominant

KEY TERMS

Epstein syndrome—A subgroup of the *MYH9*-related disorders characterized by the platelet disorder, kidney disease, and hearing loss.

Fechtner syndrome—A subgroup of the *MYH9*-related disorders characterized by the platelet disorder and inclusion bodies in the white blood cells, kidney disease, hearing loss, and cloudiness of the eye.

Inherited giant platelet disorder (IGPD)—A group of hereditary conditions that cause abnormal blood clotting and other conditions.

May-Hegglin anomaly—A subgroup of the *MYH9*-related disorders characterized by the platelet disorder and inclusion bodies in the white blood cells.

Myosin heavy chain 9 (*MYH9*)-related disorders (*MYH9*-RD)—A group of inherited macrothrombocytopenias caused by mutations in the *MYH9* gene that cause abnormal blood clotting and other symptoms.

Platelets—Small disc-shaped structures that circulate in the blood stream and participate in blood clotting.

Sebastian syndrome—A subgroup of the *MYH9*-related disorders characterized by the platelet disorder and inclusion bodies in the white blood cells.

means that only one parent has to pass on the gene mutation in order for the child to be affected with the syndrome.

Genetic studies in the year 2000 proved that *MYH9*-related disorders are due to a mutation in the gene that encodes a specific enzyme known as non-muscle myosin heavy chain 9 (the *MYH9* gene). The gene locus is 22q13.1, or the 13th band of the q arm of chromosome 22. Research determined that mutations in the same gene are responsible for four subgroups: Sebastian syndrome, May-Hegglin anomaly, Epstein syndrome, and Fechtner syndrome.

Demographics

MYH9-related disorders are extremely rare. The incidence of all four subgroups is limited; only 257 affected families had been reported in the medical literature as of 2015. Due to the very small number of cases, demographic trends for the disease have not been established.

Affected individuals have been identified in Caucasian, Japanese, African-American, Spanish, and Saudi Arabian families, so there does not seem to be any clear ethnic pattern to the disease. Both males and females appear to be affected with the same probability.

Signs and symptoms

The symptoms of *MYH9*-related disorders include bleeding problems, hearing problems, kidney (renal) disease, and cloudiness of the eye (cataract), which further distinguishes the subgroups. All four *MYH9*-related disorder subgroups are characterized by megathrombocytopenia (low numbers of large platelets), with Sebastian syndrome and May-Hegglin anomaly presenting small alterations (inclusion bodies) in the white blood cells. Epstein syndrome does not present with the white blood cell inclusion bodies, rather is distinguished by the additional symptoms of kidney disease and hearing loss. Fechtner syndrome includes all of the symptoms observed in Epstein syndrome, and includes the presentation of cataracts.

The physical symptoms of *MYH9*-related disorders are a propensity for nosebleeds, bleeding from the gums, mildly increased bleeding time after being cut, and a tendency to bruise easily. Women may experience heavier than normal menstrual bleeding. People with *MYH9*-related disorders may experience severe hemorrhage after undergoing surgery for any reason. Some individuals with *MYH9*-related disorders, particularly Sebastian syndrome, may not have any observable physical signs of the disorder at all.

Diagnosis

Diagnostic blood tests to confirm the decreased blood clotting function seen in *MYH9*-related disorders may include a complete blood count (CBC) to determine the number of platelets in a blood sample, blood coagulation studies, or platelet aggregation tests. Further quantitative analysis of the affected cellular receptors may be performed using flow cytometry or fluorescent and electron microscopy. DNA sequence-based procedures such as whole exome sequencing may provide further insight into the disease.

There are several other disorders, including non-genetic diseases, which may cause symptoms similar to those seen in *MYH9*-related disorders. A family history of easy bleeding or bruising is an important clue in diagnosing *MYH9*-related disorders. Once the hereditary nature of the disease is confirmed, establishing a dominant inheritance pattern can separate *MYH9*-related disorders from other inherited giant platelet disorders.

QUESTIONS TO ASK YOUR DOCTOR

- What is an inherited giant platelet disorder, and how do *MYH9*-related disorders differ from other forms of this condition?
- What are the most serious medical problems that arise because of *MYH9*-related disorders?
- What kinds of treatments or medications are available for the control of *MYH9*-related disorders?
- Is it necessary to have periodic medical check-ups to monitor the progress of my *MYH9*-related disorder?

Microscopic studies of the blood can reveal the enlarged platelets and the specific shape and structure characteristics associated with *MYH9*-related disorders. These characteristics include a shape that is less disc-like than normal platelets. There are also bluish inclusions, or small foreign bodies, observed in the white blood cells.

Genetic sequencing to confirm the presence of a mutation on the *MYH9* gene is another method to positively diagnose Sebastian syndrome, although this would rarely be performed in lieu of other methods.

Treatment and management

No treatment is required for the majority of people affected with *MYH9*-related disorders. After surgery, platelet transfusion may be required in order to avoid the possibility of hemorrhage. People diagnosed with *MYH9*-related disorders should be made aware of the risks associated with excessive bleeding. There have been two completed clinical trials undertaken to evaluate and develop therapies for *MYH9*-related disorders and two that were recruiting subjects as of 2015. Treatment of *MYH9*-related disorders with an agonist (eltrombopag) to stimulate platelet production was evaluated in a small-group phase-2 clinical trial in Italy in 2010 with favorable results. A larger observational clinical trial in France collected data from 360 patients from 2009 to 2015, examining the phenotype and genotype correlations of patients with *MYH9* mutations.

Prognosis

People with *MYH9*-related disorders can be expected to have a normal lifespan. The main risk for some patients is the chance of severe bleeding after surgery or injury.

Myopia

Definition

Myopia is the medical term for nearsightedness. Myopia is caused when refracted parallel rays of light are brought into focus in front of the retina of a resting eye rather than directly onto the retina. People with myopia see objects more clearly when they are close to the eye, while distant objects appear blurred or fuzzy.

Description

To understand myopia, it is necessary to have a basic knowledge of the main parts of the eye's focusing system: the cornea, the lens, and the retina. The cornea is a tough, transparent, dome-shaped tissue that covers the front of the eye (not to be confused with the white, opaque sclera). It lies in front of the iris (the colored part of the eye). The lens is a transparent, double-convex structure located behind the iris. The retina is a thin membrane that lines the rear of the eyeball. Light-sensitive retinal cells convert incoming light rays into electrical signals

that are sent along the optic nerve to the brain, which then interprets the images.

In people with normal vision, parallel light rays enter the eye and are bent by the cornea and lens (in a process called refraction) to focus precisely on the retina, providing a crisp, clear image. In the myopic eye, the focusing power of the cornea (the major refracting structure of the eye) and the lens is too great with respect to the length of the eyeball. Light rays are bent too much, and they converge in front of the retina. This inaccuracy is called a refractive error. In other words, an overfocused fuzzy image is sent to the brain.

There are many types of myopia. Some common types include:

- physiologic
- pathologic
- acquired

By far the most common form, physiologic myopia develops in children sometime between the ages of five and ten and gradually progresses until the eye is fully

This illustration compares the difference between a normal eye shape and light refraction versus a myopic eye. (Gale)

Myopia. (Shutterstock/Mrs_Bazilio)

grown. Physiologic myopia may include refractive myopia (the cornea and lens-bending properties are too strong) and axial myopia (the eyeball is too long). Pathologic myopia is a far less common abnormality. This condition begins as physiologic myopia, but rather than stabilizing, the eye continues to enlarge at an abnormal rate (progressive myopia). This more advanced type of myopia may lead to degenerative changes in the eye (degenerative myopia). Acquired myopia occurs after infancy. This condition may be seen in association with uncontrolled diabetes and certain types of cataracts. Anti-hypertensive drugs and other medications can also affect the refractive power of the lens.

Genetic profile

Eye care professionals have debated the role of genetics in the development of myopia for many years. Some believe that a tendency toward myopia may be inherited, but that the actual disorder results from a combination of environmental and genetic factors. Environmental factors include close work; work with computer monitors or other instruments that emit some light (e.g., electron microscopes, photographic equipment, or lasers); emotional stress; and eye strain. Recent epidemiological data has shown outdoor activity as a key environmental determinant of myopia. Studies in both Singaporean and Australian children correlate more time spent outdoors with less myopic refraction regardless of the indoor or outdoor activity. Twin studies have provided the strongest evidence of the role of heredity in

myopia. The degree of refractive error is seen in monozygotic twins when compared to dizygotic twins.

A variety of genetic patterns for inheriting myopia have been suggested, ranging from a recessive pattern with complete penetrance in people who are homozygotic for myopia to an autosomal dominant pattern; an autosomal recessive pattern; and various mixtures of these patterns. One explanation for this lack of agreement is that the genetic profile of high myopia (defined as a refractive error greater than -6 diopters) may differ from that of low myopia. Some researchers believe that high myopia is determined by genetic factors to a greater extent than low myopia.

The lack of clear consensus concerning the precise role of heredity in myopia may be due to the sensitivity of the human eye to very small changes in its anatomical structure. Since even small deviations from normal structure cause significant refractive errors, it may be difficult to single out any specific genetic or environmental factor as their cause.

Genetic markers and gene mapping

Since 1992, genetic markers that may be associated with genes for myopia have been located on human chromosomes 1, 2, 12, and 18. There is some genetic information on the short arm of chromosome 2 in highly myopic people. Genetic information for low myopia appears to be located on the short arm of chromosome 1, but it is not known whether this information governs the structure of the eye itself or vulnerability to environmental factors.

In 1998, a team of American researchers presented evidence that a gene for familial high myopia with an autosomal dominant transmission pattern could be mapped to human chromosome 18 in eight North American families. The same group also found a second locus for this form of myopia on human chromosome 12 in a large German/Italian family. In 1999, a group of French researchers found no linkage between chromosome 18 and 32 French families with familial high myopia. These findings have been taken to indicate that more than one gene is involved in the transmission of the disorder.

The heritability of high-grade myopia has been confirmed. Multiple high-grade myopia genetic loci have been identified, and confirmatory studies identifying high-grade and moderate myopia loci have also occurred. By 2021, more than 125 myopia susceptibility genes were documented in “Online Mendelian Inheritance in Man” (OMIM).

A study published in 2020 identified some previously unknown genetic mechanisms involved with myopia. Researchers identified about 1,000 genetic variations in nearly 450 genes that likely contribute to, or account for, many cases of moderate or severe myopia. Interestingly, genes involved in governing circadian rhythm (sleep and wake cycles) and genes responsible for pigmentation of the eyes, skin, and hair are also involved in myopia. Identification of these genetic markers and use of a polygenic risk score may help to predict which children will develop myopia and may provide clues about how to prevent and treat myopia.

Family studies

It has been known for some years that a family history of myopia is one of the most important risk factors for developing the condition. Only 6% to 15% of children with myopia come from families in which neither parent is myopic. In families with one myopic parent, 23% to 40% of the children develop myopia. If both parents are myopic, the rate rises to 33% to 60% for their children. One American study found that children with two myopic parents are six times as likely to develop myopia themselves as children with only one or no myopic parents. The precise interplay of genetic and environmental factors in these family patterns, however, is not yet known.

One multigenerational study of Chinese patients indicated that third-generation family members had a higher risk of developing myopia even if their parents were not myopic. The researchers concluded that, at least in China, the genetic factors in myopia have remained constant over the past three generations, while the environmental factors have intensified. The increase in the

percentage of people with myopia over the last 50 years in the United States has led American researchers to the same conclusion.

Demographics

Myopia is the most common eye disorder in humans around the world, reaching epidemic levels. In various reports, incidence frequently varies with age, sex, race, ethnicity, occupation, environment, and other factors. Myopia is more common in Central and Eastern Europe than in Northern Europe, Britain, and the United States. It is also very common in certain populations, such as Chinese, Japanese, Arab, and Jewish groups. Myopia is uncommon in black, Nubian, and Sudanese persons.

Myopia is a leading cause of blindness worldwide and the leading cause of preventable visual impairment in children. In 2020, the prevalence of refractive error in the United States is reported in multiple studies at 30% and is expected to rise to 50% by 2050. It has been reported that the incidence in females is higher, and onset is earlier, than in males and that white people have a significantly higher prevalence of the condition than African Americans. The Chinese and Japanese populations have one of the highest rates of myopia at greater than 50% to 70%.

Other factors that affect the demographic distribution of myopia are income level, education, and residential location. Myopia also appears to be more prevalent among people who perform a great deal of near-distance work for prolonged periods. Other factors, including nutrition, smoking during pregnancy, and exposure to digital screens may increase risk for myopia, but as of 2021, the relationships among these environmental and behavioral factors and myopia remained unclear.

Signs and symptoms

Myopia is caused by an elongation of the eyeball. The oblong (as compared to normal spherical) shape of the myopic eye causes the cornea and lens to focus at a point in front of the retina. A more precise explanation is that there is an inadequate correlation between the focusing power of the cornea and lens and the length of the eye.

People are generally born with a small amount of hyperopia (farsightedness), but that decreases as the eye grows, and myopia does not become evident until later. This change is one reason why some researchers think that myopia is an acquired, rather than inherited, trait.

The symptoms of myopia are blurred distance vision, eye discomfort, squinting, and eye strain.

KEY TERMS

Accommodation—The ability of the lens to change its focus from distant to near objects. It is achieved through the action of the ciliary muscles that change the shape of the lens.

Cornea—The transparent structure of the eye over the lens that is continuous with the sclera in forming the outermost, protective, layer of the eye.

Diopter (D)—A unit of measure for describing refractive power.

Epi-LASIK—A surgical procedure that uses a blunt, plastic oscillating blade called an epithelial separator to cut a flap in the cornea.

Laser-assisted in-situ keratomileusis (LASIK)—A surgical procedure that uses a cutting tool and a laser to modify the cornea and correct moderate to high levels of myopia.

Laser-assisted sub-epithelial keratomileusis (LASEK)—A surgical procedure in which the epithelium is loosened on the corneal surface. The loosened epithelium is then reflected away from the cornea, and laser ablation performed.

Lens—The transparent, elastic, curved structure behind the iris (colored part of the eye) that helps to focus light on the retina.

Optic nerve—A bundle of nerve fibers that carries visual messages from the retina in the form of electrical signals to the brain.

Orthokeratology—A method of reshaping the cornea using a contact lens. It is not considered a permanent method to reduce myopia.

Peripheral vision—The ability to see objects that are not located directly in front of the eye. Peripheral vision allows people to see objects located on the side or edge of their field of vision.

Photorefractive keratectomy (PRK)—A procedure that uses an excimer laser to make modifications to the cornea and permanently correct myopia.

Radial keratotomy (RK)—A surgical procedure involving the use of a diamond-tipped blade to make several spoke-like slits in the peripheral (non-viewing) portion of the cornea to improve the focus of the eye and correct myopia by flattening the cornea.

Refraction—The bending of light rays as they pass from one medium through another. Used to describe the action of the cornea and lens on light rays as they enter the eye. Also used to describe the determination and measurement of the eye's focusing system by an optometrist or ophthalmologist.

Refractive eye surgery—A general term for surgical procedures that can improve or correct refractive errors by permanently changing the shape of the cornea.

Retina—The light-sensitive layer of tissue in the back of the eye that receives and transmits visual signals to the brain through the optic nerve.

Visual acuity—The ability to distinguish details and shapes of objects.

Diagnosis

The diagnosis of myopia is typically made during the first several years of elementary school, when a teacher notices a child having difficulty seeing the chalkboard, reading, or concentrating. The teacher or school nurse often recommends an eye examination by an ophthalmologist or optometrist. An ophthalmologist—MD or DO (Doctor of Osteopathy)—is a medical doctor trained in the diagnosis and treatment of eye problems. Ophthalmologists also perform eye surgery. An optometrist (OD) diagnoses, manages, and/or treats eye and visual disorders. In many states, optometrists are licensed to use diagnostic and therapeutic drugs.

A patient's distance vision is tested by reading letters or numbers on a chart posted a set distance away (usually 20 ft. [7 m]). The doctor asks the patient to view images through a

variety of lenses to obtain the best correction. The doctor also examines the inside of the eye and the retina. An instrument called a slit lamp is used to examine the cornea and lens. The eyeglass prescription is written in terms of diopters (D), which measure the degree of refractive error. Mild to moderate myopia usually falls between -1.00D and -6.00D. Normal vision is commonly referred to as 20/20 to describe the eye's focusing ability at a distance of 20 ft. (7 m) from an object. For example, 20/50 means that a myopic person must stand 20 ft. away from an eye chart to see what a normal person can see at 50 ft. (7 m). The larger the bottom number is, the greater the degree of myopia.

Treatment and management

People with myopia have three main options for treatment: optical devices, such as specialized eyeglasses

and contact lenses; refractive eye surgery; and intraocular surgical procedures. Recent clinical trials have tested new therapeutic options to slow the progression of myopia in children. Treatments tested include atropine eye drops and pirenzepine 2% gel. Atropine is a non-selective muscarinic antagonist that clinical trials showed significantly reduced the progression of myopia by 77%. Pirenzepine gel is a selective M-1 antagonist for the M1 muscarinic receptor that negates the unwanted side effects of atropine (mydriasis and cycloplegia) and when applied twice daily, it can reduce the progression of myopia by 50%. However, regulatory and financial challenges have plagued the development of atropine drops, and studies of pirenzepine have ended.

Optical devices

EYEGLASSES. Eyeglasses are the most common method used to correct myopia. Concave glass or plastic lenses are placed in frames worn in front of the eyes. The lenses are ground to the thickness and curvature specified in the eyeglass prescription. The lenses cause the light rays to diverge so that they focus further back, directly on the retina, producing clear distance vision.

CONTACT LENSES. Contact lenses are a second option for treatment. They are extremely thin round discs of plastic that are worn on the eye in front of the cornea. Although there may be some initial discomfort, most people quickly grow accustomed to contact lenses. Hard contact lenses, made from a material called PMMA, are virtually obsolete. Rigid gas permeable lenses (RGP) are made of plastic that holds its shape but allows the passage of some oxygen into the eye. Some believe that RGP lenses may halt or slow the progression of myopia because they maintain a constant, gentle pressure that flattens the cornea. In 2004, results of a NEI-sponsored study called the Contact Lens and Myopia Progression (CLAMP) Study, were published. Researchers found that RGP contact lenses slowed the progression of myopia in young children. They also found that RGP contact lenses did not slow the growth of the eye, responsible for the majority of myopia in children. Instead of slowing the growth of the eye, RGP lenses kept the cornea from changing shape more than soft contact lenses did.

Soft contact lenses are made of flexible plastic and can be up to 80% water. Soft lenses offer increase comfort and the advantage of extended wear; some can be worn continuously for up to one week. While oxygen passes freely through soft lenses, bacterial contamination and other problems can occur, requiring replacement of lenses on a regular basis. It is very important to follow the cleaning and disinfecting regimens prescribed, because protein and lipid buildup can occur on the lenses, causing discomfort and/or increasing the risk of infection.

Contact lenses offer several benefits over glasses, including better vision, less distortion, clear peripheral vision, and cosmetic appeal. In addition, contacts will not fog up from perspiration or changes in temperature.

Refractive eye surgery

For people who find glasses and contact lenses inconvenient or uncomfortable, and who meet selection criteria in terms of age, degree of myopia, or general health, refractive eye surgery is a third treatment alternative. Radial keratotomy was the first such procedure developed, but it has been replaced since the mid-1990s by photorefractive keratectomy (PRK), laser-assisted in-situ keratomileusis (LASIK), Epi-LASIK, and laser-assisted sub-epithelial keratomileusis (LASEK). Refractive eye surgery improves myopic vision by permanently changing the shape of the cornea so that light rays focus properly on the retina. These procedures are performed on an outpatient basis and generally take 10 to 30 minutes.

PHOTOREFRACTIVE KERATECTOMY (PRK). PRK involves the use of a computer to measure the shape of the cornea. Using these measurements, the surgeon uses a computer-controlled excimer laser to make modifications to the cornea. The PRK procedure flattens the cornea by vaporizing small amounts of tissue from the cornea's surface, thereby improving the cornea's refractive properties in focusing light on the retina. The ultra-thin, outer layer of the eye (epithelium) is removed completely by laser energy during the PRK procedure, and it eventually grows back. PRK was approved by the Food and Drug Administration (FDA) for myopia in 1995, and the first excimer lasers used to perform PRK have been improved significantly in terms of size, efficiency, and accuracy. PRK can treat mild to moderate forms of myopia.

LASER-ASSISTED IN-SITU KERATOMILEUSIS (LASIK). LASIK has been approved by the FDA for several different laser platforms. About five million procedures have been performed in the United States since the approval of the excimer laser for refractive surgery in late 1995. It is recommended for moderate to severe cases of myopia. LASIK is perhaps best thought of as PRK performed under a flap instead of on the corneal surface. The flap is flipped back to expose the inner layers of the cornea. The cornea is treated with a laser to change the shape and focusing properties, and then the flap is replaced. For myopic LASIK ablations, most of the laser energy is directed at the center of the treatment zone, and the central cornea is thus flattened.

LASER-ASSISTED SUB-EPITHELIAL KERATOMILEUSIS (LASEK). In a LASEK procedure, the epithelium is chemically loosened using dilute alcohol on the corneal surface. The loosened epithelium is then reflected away from the

cornea, and laser ablation is performed. The procedure preserves the extremely thin epithelial layer by lifting it from the eye's surface before using a laser for reshaping. After the LASEK procedure, the epithelium is replaced on the eye's surface.

EPI-LASIK. In Epi-LASIK, the surgeon uses a blunt, plastic oscillating blade called an epithelial separator to cut a flap in the cornea. Instead of the alcohol used in LASEK to loosen the epithelial sheet, the epithelial separator is used to separate the sheet from the eye. This avoids the possibility of an adverse reaction from the alcohol. Because it is more difficult to create the epithelial flap in people with steeper corneas (who have higher amounts of myopia), the procedure is considered more appropriate for people with less-steep corneas (who have low myopia).

Intraocular surgical procedures

These procedures involve extraction of the clear lens with or without lens implantation and the use of intraocular lens (IOL) implants. IOLs have been used since 1999 to correct large refractive errors in myopia. An IOL is a microscopic lens that can be placed inside the eye to correct certain vision problems. For patients who are extremely nearsighted and may have contraindications to LASIK, an IOL may be implanted in front of the iris to correct their distance vision and provide normal focusing ability and near vision. Although IOLs are intended to be permanent, the procedure is reversible.

Risks

All of these surgical procedures carry risks. The most serious are corneal scarring, corneal rupture, infection, flap problems, dry eye, cataracts, and loss of vision. The National Eye Institute (NEI) warns that before agreeing to refractive surgery, patients should get a clear picture of what they can expect. Surgeons should explain the risks and possible complications as well as potential side effects.

Since refractive eye surgery does not guarantee 20/20 vision, it is important to have realistic expectations before choosing this treatment. For example, the American Academy of Ophthalmology (AAO) reports that nine out of ten patients achieve 20/20 vision, but 20/20 does not always mean perfect vision. Detailed, precise vision may be slightly diminished. Even if the patient gains near-perfect vision, irritating side effects are also possible, such as post-operative pain, poor night vision, variation in visual acuity, light sensitivity and glare, and optical distortion. Finally, refractive eye surgeries are considered elective procedures and are rarely covered by insurance plans.

QUESTIONS TO ASK YOUR DOCTOR

- What are the treatment options for myopia?
- How do I choose between contact lenses and glasses?
- If I have other eye conditions, how can I best manage them together?
- Am I a candidate for eye surgery?

Alternative treatments

Some eye care professionals recommend treatments to help improve circulation, reduce eye strain, and relax the eye muscles. It is possible that by combining exercises with changes in behavior, the progression of myopia may be slowed or prevented. Alternative treatments include visual therapy (also referred to as vision training or eye exercises); discontinuing close work; reducing eye strain (taking a rest break during periods of prolonged near-vision tasks); and wearing bifocals to decrease the need to accommodate when doing close-up work.

Clinical trials

As of 2021, there were more than 140 clinical trials on myopia planned, or underway, sponsored by the National Institutes of Health (NIH) and other agencies. Clinical trial information is constantly updated by NIH, and the most recent information on myopia trials can be found at <http://clinicaltrials.gov>.

Prognosis

Glasses and contact lenses can (but not always or completely) correct the patient's vision to 20/20. Refractive surgery can make permanent improvements for the right candidates.

While the genetic factors that influence the transmission and severity of myopia cannot be changed, some environmental factors can be modified. They include spending time outdoors, reducing close work, reading and working in good light, taking frequent breaks when working at a computer or microscope for long periods of time, maintaining good nutrition, and practicing visual therapy (when recommended).

Eye strain can be prevented by using sufficient light for reading and close work, and by wearing corrective lenses as prescribed. Everyone should have regular eye examinations to see whether their prescription has changed or whether any other problems have developed. This

is particularly important for people with high (degenerative) myopia who are at a greater risk of developing retinal detachment, retinal degeneration, glaucoma, or other problems.

Myotonia congenita

Definition

Myotonia congenita (MC) is a genetic disorder of the muscle fiber membranes in skeletal muscle. It is classified as a channelopathy, because it is caused by the dysfunction of chloride ion channels. The disorder is characterized by muscle hyperexcitability, leading to difficulty relaxing muscles after contracting them (myotonia); muscular stiffness and rigidity; enlargement (hypertrophy) of some muscles or muscle groups; and temporary cramping sensations or weakness in the muscles.

MC has two forms: Thomsen disease (THD), caused by autosomal dominant mutations in the *CLCN1* gene on chromosome 7, and Becker disease, caused by autosomal recessive mutations in the same gene. Thomsen disease is named for a Danish physician, Asmus Julius Thomsen, who had the disease himself, recognized that it is a hereditary disorder when three of his sons developed symptoms of it, and published a description of it in 1876. Becker disease is named for Peter Emil Becker, a German geneticist who identified the autosomal recessive form of myotonia congenita in 1966. Becker disease is the more common and more severe form of MC.

Description

Both forms of MC are marked by difficulty relaxing skeletal muscles after voluntary contraction, by muscle hypertrophy, and by general stiffness of the muscles.

Thomsen disease

In Thomsen disease, the symptoms first appear during infancy through two to three years of age and are most likely to affect the muscles of the hands, legs, tongue, and eyelids. In some cases, patients with Thomsen disease develop spasms of the muscles in the face and trunk. Spasms in the muscles that control the movement of the eyeballs may cause temporary double vision or crossed eyes (strabismus), while myotonia in the muscles of the throat or tongue may cause occasional difficulty in chewing, swallowing, or speaking after a period of silence.

Males with Thomsen disease are generally more severely affected than females, although the severity of symptoms can vary considerably among members of the same family. Women with THD often find that their symptoms are more severe during menstrual periods and pregnancy and are relieved after menopause. Some patients also report that cold weather aggravates the symptoms of Thomsen disease, while warm weather or alcoholic beverages relieve the symptoms. Thomsen

KEY TERMS

Channelopathy—A type of disease caused by disturbances in the function of ion channels or the proteins that regulate them. Channelopathies may be either genetic or acquired later in life.

Congenital—Present at birth.

Hyperexcitability—The abnormally intense response of muscle fiber membranes to stimulation.

Ion channels—Proteins or protein complexes that open or close the flow of ions (atoms or molecules with a positive or negative electrical charge) across cell membranes.

Loss-of-function mutation—Any mutation that causes a gene to lose its ability to encode a protein, either partially or completely.

Malingering—Exaggerating or faking the symptoms of a physical or psychiatric illness in order to avoid work, school, or military service; obtain fraudulent financial compensation; or attract sympathy or attention.

Myotonia—Sustained contraction or delayed relaxation of a muscle following voluntary contraction of that muscle.

Percussion—A technique used in physical diagnosis in which the examiner taps on the surface of the body to determine the condition of the structure beneath the skin. Percussion is used when examining a patient for myotonia congenita to see whether the tapping will cause the muscle beneath the skin to contract.

Warm-up phenomenon—The progressive easing of the myotonic contraction of a muscle (in a patient with myotonia congenita) with repeated voluntary contractions of the muscle.

disease, however, is not progressive, which means that the symptoms do not get worse as the patient grows older, nor do they move from one part of the body to another.

Becker disease

The term “congenital” is something of a misnomer when applied to the Becker form of MC, because the symptoms of this subtype do not appear until later childhood (about age four) or even as late as age 18. The symptoms of Becker disease are more severe than those of Thomsen disease, with myotonia and muscle stiffness becoming progressively worse with age. The muscular symptoms also progress from the legs upward to other

parts of the body in Becker disease, most often to the arms, face, throat, and trunk.

Muscle hypertrophy is usually more marked in Becker disease than in Thomsen disease; paradoxically, muscle weakness and pain (myalgia) are also more common in the Becker form of MC than in Thomsen disease. Patients with Becker disease, however, are not usually affected by exposure to cold.

Genetic profile

Both subtypes of myotonia congenita are caused by loss-of-function mutations in the *CLCN1* gene on the long arm of chromosome 7 at 7q35. A loss-of-function mutation is one in which the gene loses part or all of its ability to encode its protein product. The *CLCN1* gene normally encodes a protein called CIC-1, which is a chloride channel (a specialized protein) that controls the flow of chloride ions into skeletal muscle cells. Under normal circumstances, the contraction and relaxation of muscle cells is coordinated so that the body or its various parts can move smoothly and efficiently. Chloride ions stabilize the electrical charge of muscle cells, preventing them from contracting abnormally. Mutations in the *CLCN1* gene, however, result in alterations in the CIC-1 channel that disrupt the flow of chloride ions into the muscle cells, resulting in the sustained muscle contractions that form the primary symptom of MC.

Thomsen disease differs from Becker disease in its pattern of inheritance, however. It is inherited in an autosomal dominant pattern, which means that only one defective copy of the *CLCN1* is needed for the offspring to develop the symptoms of the disorder, although the severity of the symptoms may vary from one family member to another.

Becker disease is inherited in an autosomal recessive pattern, which means that a child must inherit two copies of a defective *CLCN1* gene, one from each parent, in order to manifest the disease. Becker disease has been reported in a number of consanguineous families, in which marriage between blood relatives increases the risk of inheriting autosomal recessive genetic disorders.

Demographics

Overall, MC is a rare disease, with an estimated worldwide prevalence of one case per million population. It is, however, much more common in northern Scandinavia than in other countries, with an estimated prevalence of one case in every 10,000 people. The Becker subtype of MC is one of 40 disorders designated as a Finnish heritage disease, which means that it is particularly common among ethnic Finns and persons of Finnish ancestry living in Sweden and northwestern Russia.

QUESTIONS TO ASK YOUR DOCTOR

- Have you ever treated a patient with either form of myotonia congenita?
- If so, what treatment(s) did you recommend?
- How effective are medications in treating myotonia congenita?
- What are the chances of our family's having a second child with MC?
- Should other family members be tested for the disorder?

Both forms of MC affect males and females with equal frequency.

Mechanisms

Recessive MC, or Becker disease, is a heritable skeletal muscle disease caused by mutated chloride channels in the muscles that do not work properly. Muscle rapidly cycles between hyper- and hypoexcitability as individual fibers switch from experiencing myotonia (causing stiffness) to the generation of plateau potentials (causing weakness), respectively. The state of the muscle depends on the strength of the signal experienced by the muscle fibers. Mild depolarization triggers myotonia, and more severe depolarization triggers the generation of a plateau potential. Both calcium and sodium ion channels are involved in creating a plateau potential. Sodium channels trigger this state, while calcium channels are responsible for maintaining it.

Signs and symptoms

The most noticeable symptom of MC is myotonia, or inability to relax the muscles after contracting them. Myotonia is most apparent after a period of rest, as when the patient is trying to get out of bed in the morning, arising from a chair, starting to run or walk after sitting or standing still for a period of time, or opening the eyelids after sneezing or blinking. Another common form of myotonia is the inability to relax a hand grip; for example, releasing a handshake or removing the hands from the steering wheel of a car after driving for a period of time.

Myotonia in people with MC may be affected by medications or psychological conditions. Certain diuretics worsen myotonia by lowering the levels of magnesium and calcium in the body, and emotional stress

worsens myotonia by stimulating the release of adrenaline/epinephrine, a hormone involved in the “fight-or-flight” reaction. Persons with MC may find themselves completely unable to move when feeling pressured or upset.

Muscle hypertrophy, found in both forms of MC, refers to the abnormal enlargement of skeletal muscles. It is not unusual for patients with MC to develop a “body builder” appearance, particularly in the muscles of the legs. As noted above, this sign of the disorder is particularly marked in Becker disease.

One distinctive sign of both types of MC is the so-called warm-up phenomenon, first noticed by Julius Thomsen and described in his 1876 report. The warm-up phenomenon refers to the gradual relaxation of a myotonic muscle when the patient intentionally contracts the muscle several times. After a few contractions, the myotonia disappears for a period of several minutes. Several different explanations have been offered for the warm-up phenomenon, but none has been universally accepted.

Diagnosis

Diagnosis of MC is based on a combination of clinical observations, diagnostic testing, and molecular genetic testing.

Thomsen disease is usually diagnosed in infants or young children when the parents or the pediatrician notice such symptoms as gagging or choking on food, stiff movements that appear to be improved when the child repeats them, frequent falls, and difficulty opening the eyes after a crying spell. The pediatrician may take a family history to see whether other family members have reported similar symptoms, and may percuss (thump or tap) the child's arm, finger, or leg muscles to elicit a myotonic response. Another common test that can be done in the doctor's office is to ask the child to grasp an object or the examiner's hand to see how quickly the child can release his or her grip.

Laboratory testing for MC may include electromyography (EMG), a technique for measuring and recording the electrical activity in skeletal muscles by means of electrodes placed on the surface of the skin or inserted into the muscle being tested. One typical EMG finding in patients with MC is repetitive spontaneous electrical activity in the muscles, known as myotonic runs. Another laboratory test that can be used to evaluate patients for MC measures the level of creatine kinase (CK) in the patient's blood serum. Creatine kinase is an enzyme found in elevated levels in the blood when muscle tissue is damaged or inflamed.

The definitive diagnosis of MC is made by molecular genetic testing for mutations in the *CLCN1* gene. About 95% of cases of MC, whether autosomal dominant or autosomal recessive, can be identified by genetic testing.

Treatment and management

There is no cure for MC, but the disorder can usually be managed by a combination of medications, physical therapy, and vocational or psychological counseling. Some patients with very mild symptoms may not require any treatment.

The medication that is most often used to treat the muscle stiffness associated with MC is mexiletine (Mexilitil), a sodium channel blocker that was originally developed to treat heart arrhythmias. Other drugs that are used to treat muscle stiffness in MC include quinine, phenytoin (an anticonvulsant drug), and procainamide. Another antiarrhythmic, tocainide, is used in Europe to treat MC but was taken off the market in the United States. Some patients with MC have been helped by dantrolene, a muscle relaxant, or carbamazepine, another anticonvulsant.

Physical therapy is often beneficial to patients with MC, because the therapist can devise individualized exercises to alleviate myotonia in specific muscle groups or areas of the patient's body.

Patients with MC sometimes need psychological counseling, because the symptoms of the disorder often appear to others as either malingered or acting out. For example, one of Julius Thomsen's three affected sons was accused of draft-dodging when he tried to explain his disability to the military physicians who examined him. It was only after two months of further examinations that the doctors recognized that his symptoms were genuine, and released him from military service.

Prognosis

Neither form of MC is a life-threatening disease or accompanied by intellectual disability; most patients can complete their education, enjoy productive lives, and have normal lifespans. However, patients with MC are at increased risk of falls, particularly when under emotional stress, and may suffer serious injuries or accidental drowning.

Myotonic dystrophy

Definition

Myotonic dystrophy is a progressive disease in which the muscles are weak and are slow to relax after contraction.

Description

There are two types of myotonic dystrophy, type 1 (DM1) and type 2 (DM2). Myotonic dystrophy, type 1 is also called Steinert's disease. Both types are inherited in an autosomal dominant manner meaning the disease can affect both males and females. Symptoms may appear at any time from infancy to adulthood. DM causes general weakness, usually beginning in the muscles of the hands, feet, neck, or face. It slowly progresses to involve other muscle groups, including the heart. DM affects a wide variety of other organ systems as well.

A severe form of DM, congenital myotonic dystrophy, may appear in newborns of mothers who have DM. Congenital means that the condition is present from birth.

Type 2 myotonic dystrophy is also known as Proximal Myotonic Myopathy (PROMM). The symptoms of DM2 include myotonia, muscle weakness, muscle pain, and stiffness. Other symptoms of this form of myotonic dystrophy include testicular failure, insulin-insensitive type 2 diabetes, cataracts, and some types of cardiac abnormalities.

Genetic profile

DM1 is caused by a mutation in a gene called myotonic dystrophy protein kinase (*DMPK*). The *DMPK* gene is located on chromosome 19. When there is a mutation in this gene, a person develops DM1. The specific mutation that causes DM1 is called a trinucleotide repeat expansion.

DM2 is caused by a mutation in the *CNBP* gene located on chromosome 3. The specific mutation that

causes DM2 is a complex expansion of CCTG nucleotides in the *CNBP* gene. The mean number of CCTG repeats that causes DM2 is 5,000, with a range between 75 to over 11,000.

Trinucleotide repeats

In the *DMPK* gene, there is a section of the genetic code where the three letters CTG are repeated a certain number of times. In people who have DM1, these letters are repeated too many times—more than 34 times—and thus this section of the gene is too big. This enlarged section of the gene is called a trinucleotide repeat expansion.

People who have repeat numbers in the normal range will not develop DM1 and cannot pass it to their children. Having more than 50 repeats causes DM1. People who have 35–49 CTG repeats have a premutation and will not develop DM1 but can pass DM1 onto their children. Having repeat numbers greater than 1,000 causes congenital myotonic dystrophy (the most severe form of DM1).

In general, the more repeats in the affected range that someone has, the earlier the age of onset of symptoms and the more severe the symptoms. However, this is a general rule. It is not possible to look at a person's repeat number and predict at what age he or she will begin to have symptoms or how the condition will progress.

Exactly how the trinucleotide repeat expansion causes myotonia, the inability to relax muscles, is not yet understood. The disease somehow blocks the flow of electrical impulses across the muscle cell membrane. Without proper flow of charged particles, the

Myotonic Dystrophy: pedigree analysis chart (Gale)

Relationship between phenotype and CTG repeat length in myotonic dystrophy

(Gale)

muscle cannot return to its relaxed state after it has contracted.

Anticipation

Sometimes when a person who has repeat numbers in the affected or premutation range has children, the expansion grows larger. This is called anticipation. A larger expansion can result in an earlier age of onset in children than in their affected parent. Anticipation happens more often when a mother passes DM1 onto her children than when it is passed from the father. Occasionally repeat sizes stay the same or even get smaller when they are passed to a person's children.

As of July 2015, it was still debated whether anticipation occurs with DM2. In addition, at this time, it is believed that there is no congenital form of DM2.

Inheritance

DM is inherited through autosomal dominant inheritance. This means that equal numbers of males and females are affected. It also means that an individual only needs one gene mutation in order to be affected. Since a person only passes one copy of each gene on to his or her children, there is a 50% or one in two chance that a person who has DM will pass it on to each of his or her children. This percentage is not changed by results of other pregnancies. A person with a premutation also has a 50%, or one in two, chance of passing the altered gene on to each of his or her children. However, whether or not his or her children will develop DM1 depends on whether the trinucleotide repeat becomes further expanded. A person who has repeat numbers in the normal range cannot pass DM1 onto his or her children.

Demographics

DM occurs in about 1 in 8,000 to 1 in 20,000 people and has been described in people from all over the world. It is unknown which percentage of myotonic dystrophy cases are type 1 versus type 2.

Signs and symptoms

There are three forms of DM1: mild DM1, classic DM1, and congenital DM1. The severity of symptoms in each form of DM1 varies between affected individuals with the same form, and not everyone will have all of the symptoms listed for each form.

Mild DM1

This form of DM1 causes weakness and delayed muscle relaxation called myotonia as well as cataracts and muscle weakness.

Classic DM1

Symptoms of classic DM1 include facial weakness and a slack jaw, drooping eyelids called ptosis, and muscle wasting in the forearms and calves. A person with DM has difficulty relaxing his or her grasp, especially in the cold. DM affects the heart muscle, causing irregularities in the heartbeat. It also affects the muscles of the digestive system, causing constipation and other digestive problems. DM may cause cataracts, retinal degeneration, low IQ, frontal balding, skin disorders, atrophy of the testicles, and diabetes. It can also cause sleep apnea—a condition in which normal breathing is interrupted during sleep. DM increases the need for sleep and decreases motivation. Severe disabilities do not set in until about 20 years after symptoms begin. Most people with myotonic dystrophy maintain the ability to walk, even late in life.

KEY TERMS

Electrocardiogram (ECG, EKG)—A test that uses electrodes attached to the chest with an adhesive gel to transmit the electrical impulses of the heart muscle to a recording device.

Electromyography (EMG)—A test that uses electrodes to record the electrical activity of muscle. The information gathered is used to diagnose neuromuscular disorders.

Muscular dystrophy—A group of inherited diseases characterized by progressive wasting of the muscles.

Sleep apnea—Temporary cessation of breathing while sleeping.

Trinucleotide repeat expansion—A sequence of three nucleotides that is repeated too many times in a section of a gene.

Congenital DM1

A severe form of DM, congenital myotonic dystrophy, may appear in newborns of mothers who have DM1. Congenital myotonic dystrophy is marked by severe weakness, poor sucking and swallowing responses, respiratory difficulty, delayed motor development, and intellectual disability. Death in infancy is common in this type.

Some people who have a trinucleotide repeat expansion in their *DMPK* gene do not have symptoms or have very mild symptoms that go unnoticed. It is not unusual for a woman to be diagnosed with DM after she has an infant with congenital myotonic dystrophy.

Myotonic dystrophy type 2 (DM2) has very similar symptoms as DM1 with most affected individuals presenting with complaints of muscle weakness. Affected individuals often have difficulties climbing stairs and standing up from a seated position. Other symptoms of DM2 include difficulties releasing a tightened fist, known as myotonia or sustained muscle contraction. Similar to DM1, individuals with DM2 may develop diabetes because of this condition and be at risk for serious heart complications, either cardiac conduction problems or cardiomyopathy. Cataracts are another symptom of DM2. Males who have this form of myotonic dystrophy may also be diagnosed with low testosterone or low sperm count, both of which can cause infertility.

Predictive testing

It is possible to test people at risk for developing DM1 and DM2 before they are showing symptoms to see

whether they inherited an expanded nucleotide repeat. This is called predictive testing. Predictive testing cannot determine the age of onset that someone will begin to have symptoms, or the course of the disease.

Diagnosis

Diagnosis of DM is not difficult once the disease is considered. However, the true problem may be masked because symptoms can begin at any age, can be mild or severe, and can occur with a wide variety of associated complaints. Diagnosis of DM begins with a careful medical history and a thorough physical exam to determine the distribution of symptoms and to rule out other causes. A family history of DM or unexplained weakness helps to establish the diagnosis.

A definitive diagnosis of DM1 and DM2 is done by genetic testing, usually by taking a small amount of blood. The DNA in the blood cells is examined, and the number of repeats in the *DMPK* gene is determined. Various other tests may be done to help establish the diagnosis, but only rarely would other testing be needed. An electromyogram (EMG) is a test used to examine the response of the muscles to stimulation. Characteristic changes are seen in DM that help distinguish it from other muscle diseases. Removing a small piece of muscle tissue for microscopic examination is called a muscle biopsy. DM is marked by characteristic changes in the structure of muscle cells that can be seen on a muscle biopsy. An electrocardiogram could be performed to detect characteristic abnormalities in heart rhythm associated with DM. These symptoms often appear later in the course of the disease.

Prenatal testing

Testing a pregnancy to determine whether an unborn child is affected is possible if genetic testing in a family has identified a *DMPK* mutation. This can be done at 10–12 weeks gestation by a procedure called chorionic villus sampling (CVS), which involves removing a tiny piece of the placenta and analyzing DNA from its cells. It can also be done by amniocentesis after 15 weeks gestation by removing a small amount of the amniotic fluid surrounding the baby and analyzing the cells in the fluid. Each of these procedures has a small risk of miscarriage associated with it, and those who are interested in learning more should check with their doctor or genetic counselor. Prenatal testing for DM2 is only available if the disease-causing mutation has already been identified in an affected individual.

Another procedure, called preimplantation diagnosis, allows a couple to have a child that is unaffected with the genetic condition in their family.

QUESTIONS TO ASK YOUR DOCTOR

- Please explain the genetic basis for myotonic dystrophy.
- How is myotonic dystrophy like muscular dystrophy, and how is it different?
- What are the stages in the progression of myotonic dystrophy over a period of years?
- What are the most serious long-term medical consequences associated with myotonic dystrophy?
- What are the similarities and differences between myotonic dystrophy type 1 and myotonic dystrophy type 2?

Treatment and management

Myotonic dystrophy cannot be cured, and no treatment can delay its progression. However, many of the symptoms it causes can be treated. Physical therapy can help preserve or increase strength and flexibility in muscles. Ankle and wrist braces can be used to support weakened limbs. Occupational therapy is used to develop tools and techniques to compensate for loss of strength and dexterity. A speech-language pathologist can provide retraining for weakness in the muscles controlling speech and swallowing.

Irregularities in the heartbeat may be treated with medication or a pacemaker. A yearly electrocardiogram is usually recommended to monitor the heartbeat. Diabetes mellitus in DM is treated in the same way that it is in the general population. A high-fiber diet can help prevent constipation. Sleep apnea may be treated with surgical procedures to open the airways or with nighttime ventilation. Treatment of sleep apnea may reduce drowsiness. Lens replacement surgery is available when cataracts develop. Pregnant woman should be followed by an obstetrician familiar with the particular problems of DM because complications can occur during pregnancy, labor, and delivery.

Wearing a medical bracelet is advisable. Some emergency medications may have dangerous effects on the heart rhythm in a person with DM. Adverse reactions to general anesthesia may also occur.

Prognosis

The course of myotonic dystrophy varies. When symptoms appear earlier in life, disability tends to become more severe. Occasionally people with DM may

require a wheelchair later in life. Children with congenital DM usually require special educational programs and physical and occupational therapy. For both types of DM, respiratory infections pose a danger when weakness becomes severe.

Myotubular myopathy

Definition

Myotubular myopathy (MTM) belongs to a rare group of developmental disorders of voluntary muscle called congenital myopathies that present as a "floppy baby" syndrome. This is a genetically inherited disorder with various abnormalities in muscle fiber development, muscle tone, and contraction. MTM refers to the pathological finding of muscle fibers with centrally located nuclei resembling the myotubule stage of muscle development.

Description

This condition is also known as centronuclear myopathy (CNM), X-linked MTM (MTM1 or XLMTM),

pericentronuclear myopathy, or type I fiber hypotrophy with central nuclei. It is primarily caused by defective maturation of the muscle. Spiro first described this disorder in 1966. The *myotubularin* gene was identified in 1996.

Muscle fibers normally undergo a complicated series of maturational changes before becoming fully functional normal adult muscle fibers. The myotubule stage is an intermediate state in the fiber maturational process. It is seen normally only in an 8- to 20-week-old fetus and is characterized by central nuclei. In MTM, the maturation is arrested at this stage, and the protein machinery of the muscle fiber needed for contraction is not fully formed. Muscles of patients with MTM thus show an overabundance of immature, poorly functional myotubular fibers.

MTM has different modes of inheritance, resulting in a wide variability of symptom onset (birth to early adulthood) and rate of symptom progression. Some researchers classify CNM and MTM as two extreme ends of a spectrum, with CNM being the milder form. Disability arises due to weakness of voluntary muscles and respiratory difficulty, progressing to death.

Genetic profile

There are three types of MTM, based on the mode of inheritance.

X-linked MTM (MTM1)

This is the most common form and is inherited usually in an X-linked recessive fashion, although *de novo* (new) mutations can occur rarely. It is due to a mutation in the myotubularin, or *MTM1*, gene that occurs on the long arm of the X chromosome at locus Xq27.3-q28. Another related gene, called *MTMRI*, is also found on the X chromosome. About 150 types of myotubularin mutations have been identified, and depending on the type, the severity of disease expression varies. Mutations that truncate the gene lead to severe or lethal disease expression. Mutations that delete part of the gene or cause misreading of the gene cause less severe disease. The gene encoding for the myotubularin protein is widely expressed, not just in the muscle. The relationship between the gene product and the disease is still being investigated.

Each cell has one pair of sex chromosomes. The female has two copies of the X chromosome, one inherited from each parent, while the male has only one X chromosome inherited from the mother and the Y chromosome inherited from the father. A mother who carries one abnormal X chromosome containing the myotubularin mutation has a 50% chance of passing it to each of her offspring. If the daughter inherits the mutation, she may not exhibit any symptoms because she has an extra normal copy; this makes her a

carrier. However, a son who inherits the mutation will express the disease because he cannot compensate for the mutated gene carried on his single X chromosome. If an affected male child has other affected male siblings, about 90% of the time the abnormal gene has been inherited from the mother in an X-linked fashion. If there are no other affected male siblings, then it is most likely a *de novo* mutation. Father-to-son transmission is not possible in *MTM1*.

Carriers of X-linked MTM

Carriers are usually females who have an abnormal gene on one of their X chromosomes. They usually do not express the disease due to compensation from the normal copy. Skewed inactivation of the X chromosome containing the normal gene leads to milder disease expression.

Autosomal dominant MTM

In this mode of inheritance, one copy of another myotubularin gene (*MTMR2*, *MTMR3*) is abnormal on an autosome, chromosome 12. Each cell has two chromosomes 12 carrying the myotubularin gene, and there are two alternate forms (alleles) in which the gene can exist. Therefore, four possible combinations of alleles can exist for this gene. If a person has one normal and one abnormal allele and expresses the normal allele, the individual will have the autosomal dominant form of MTM. Both males and females are equally affected, and the disease is passed on from generation to generation. There will usually be one affected person in each generation, and each child has a 50% chance of inheriting the abnormal gene. Father-to-son transmission is possible.

Autosomal recessive MTM

This can occur in three ways. The affected person can have two abnormal alleles of the myotubularin gene or can have two different types of abnormal alleles. Finally, the affected person can have one normal and one abnormal allele and express the abnormal allele. Males and females are affected equally. Some ethnic predilections occur due to consanguinity where each parent of an affected child is a non-expressing carrier with both a normal and an abnormal allele. Therefore, each of their children has a 25% chance of being affected and a 50% chance of being a non-expressing carrier.

Demographics

MTM is a rare condition; accurate estimates are unavailable. Approximate estimates in 2014 for X-linked MTM were estimated to be 1 in 50,000 newborn males. Unlike other congenital myopathies, there is a relatively high incidence in Africans.

KEY TERMS

Allele—One of two or more different genes encoding specific and inheritable characteristics that occupy corresponding locations on a pair of chromosomes.

Amniotic fluid—Fluid contained in a sac within the uterus that surrounds and protects the fetus during its development.

Autosomal—Relating to any chromosomes besides the X and Y sex chromosomes. Human cells contain 22 pairs of autosomes and one pair of sex chromosomes.

Carrier—An individual who possesses an unexpressed abnormal gene of a recessive genetic disorder.

Contracture—An abnormal and usually permanent shortening and contraction of a muscle or tendon that causes a deformity or subnormal range of movement.

Creatine kinase (CK)—An enzyme that is normally found in the skeletal or voluntary muscle and cardiac muscle; very high levels in the blood usually indicate breakdown of either heart or voluntary muscle.

Cryptorchidism—Failure of descent of the testis from the abdominal cavity into the scrotum.

De novo—Latin term for “new.”

Dolicocephaly—Elongated and narrow skull shape due to premature closure of the sagittal suture that runs from the forehead to the back of the skull.

Electromyography—A test that assesses the activity of the muscles and the nerves that supply the muscles; one part of the test involves passing electrical current through the nerves and studying the response of the muscles to it, while the other part involves studying muscle activity by inserting a thin needle into it.

G-tube—A gastrostomy tube, which is inserted surgically into the stomach and used for feeding and for administering medications.

Hydrocephalus—The excess accumulation of cerebrospinal fluid around the brain, often causing enlargement of the head.

Hypotonia—Low or poor muscle tone, resulting in floppy limbs.

Linkage analysis—A method of finding mutations based on their proximity to previously identified genetic landmarks.

Lordosis—An abnormal curvature of the spine in which the lumbar, or lower section, is excessively curved (also known as pigeon chest).

Myopathy—Any abnormal condition or disease of the muscle.

Myotubule—An intermediate stage in muscle fiber development, where the fiber is tubular with a centrally placed nucleus, instead of a peripheral eccentric nucleus.

Polyhydramnios—A condition in which there is too much fluid around the fetus in the amniotic sac.

Ptosis—Drooping of the upper eyelid.

Pulmonologist—A physician who specializes in lung diseases.

Scoliosis—Abnormal curvature of the spine, usually defined as greater than ten degrees to the right or left as the doctor faces the patient.

Skewed inactivation—Random inactivation of either the paternally or maternally derived X chromosome in the female, also called lyonization, occurring early in embryonic development.

Spherocytes—Abnormal spherically shaped red blood cells caused by a disorder in the cell membrane; normally, the red blood cell is biconcave in shape.

Stent—A tubular device made of metal or plastic that is inserted into a body duct or tube to prevent collapse, blockage, or overgrowth.

Tendon reflex—Reflex contraction of the muscle that is observed by tapping on its tendon.

Tracheostomy—An opening surgically created in the trachea (windpipe) through the neck to improve breathing.

Signs and symptoms

There is a wide spectrum of clinical features seen in MTM depending on the mode of inheritance, but the basic problem arises from poor muscle tone interfering with posture, locomotion, and muscle strength. In general, the earlier the symptoms present, the more severe and progressive the disorder.

X-linked MTM

This is the most severe and most studied form, which presents at birth or even prior to birth, typically occurring in males. Mothers who are pregnant with affected boys experience polyhydramnios, which is an excessive amount of amniotic fluid due to decreased fetal swallowing of the fluid. Affected boys also exhibit decreased

movements in utero. Fetal cardiac rhythm disturbances can also occur. Newborn males with MTM have a weak cry, are floppy at birth, have difficulty suckling and swallowing, exhibit severe generalized muscle weakness, and have serious respiratory difficulty. Life-threatening difficulties are caused by respiratory and swallowing problems. In very severe cases, the infants succumb to the disease quite early in the absence of adequate respiratory support, and death can occur within a few days of birth. Intermediate form of X-linked MTM occurs in adolescents who develop severe muscle weakness and become non-ambulatory between early and middle life. Mild forms can present in early adulthood with facial weakness, eye muscle weakness, and mild gait difficulty.

Affected boys have a long slender body with long fingers and toes and appear frail. Length is disproportional to body weight as skeletal growth surpasses muscle growth. This is thought to be a result of endocrine dysfunction leading to rapid skeletal growth. The head can be dolichocephalic (elongated) or enlarged due to hydrocephalus. Other facial features, such as high arched palate, dental abnormalities, puffy or droopy eyelids (ptosis) due to eye muscle weakness, and squint, occur. Poor muscle tone leads to decreased blinking during the day and incomplete eye closure during sleep, causing eye irritation. Speech is soft and nasal. The affected children adopt a frog-leg posture due to hypotonia (decreased muscle tone). Skeletal deformities, such as pigeon-chest, scoliosis, and joint dislocations, also occur due to hypotonia. Tendon reflexes are absent. Over time, contractures occur in the hip, knee, and ankle joints, making walking difficult. Swallowing difficulty leads to drooling with aspiration of oral secretions into the lungs that can result in pneumonia. Intelligence and cognitive development is usually normal unless there has been a significant birth injury or respiratory distress with prolonged lack of oxygen.

Other associated medical problems include spherically shaped abnormal red blood cells (spherocytes), anemia, enlarged spleen, and gallstones. Peliosis hepatis is a disorder in which the liver has large blood-filled cysts that can rupture into the abdominal cavity and cause massive bleeding and death. Some patients have a vitamin K responsive bleeding disorder. Other genital and urinary problems like undescended testes (cryptorchidism) and kidney stones also occur. Constipation can be a result of poor gut motility or overall physical immobility. Hearing and vision are unaffected.

Autosomal dominant MTM

This is the least severe form and tends to affect males twice as often as females. It presents in late childhood or early adulthood and progresses slowly. It is less common

than X-linked MTM. The major problem is proximal muscle weakness in the shoulders and hips with leg cramps. Ptosis, joint contractures, and a mild tremor can also be seen.

Autosomal recessive MTM

This can begin at birth, in late infancy, or in early adulthood, but it is much less severe than X-linked MTM. Females are slightly more affected than males. Common features include weakness of eye muscles and face; thin face with a high, arched palate; hypotonia; mild generalized weakness, including neck, trunk, shoulder, and hip muscles; delayed motor milestones; and respiratory distress. Affected individuals develop a waddling gait due to hip muscle weakness and have lordosis and clubfeet. Infants have a slowly progressive paralysis of eye muscles, loss of facial expression, and continuing limb weakness as they grow. Seizures or blackout spells can occur. Intelligence can be normal, or mental deficiency can occur. This condition progresses slowly and eventually leads to loss of ambulation. Many children are never able to run or participate in games with their peers.

Carriers

These are usually women, and they present with mild facial weakness, spinal deformities such as scoliosis, flat feet, mild muscle weakness, and gait difficulty.

Diagnosis

There is a considerable overlap in symptom severity among the three forms of MTM in affected males. Thus, in a family with a single affected male child, reliance on clinical features alone to diagnose the pattern of inheritance, to predict its prognosis, and to counsel the family regarding the chance of having another affected child becomes difficult. Detailed and thorough family history should be obtained to detect other family members with possible MTM. There is no absolute biochemical, DNA, or pathology test that can tell conclusively the pattern of inheritance in an isolated case. A history of spontaneous abortions or death of male infants in the neonatal period is a clue to X-linked transmission.

Creatine kinase (CK) is an enzyme that indicates muscle breakdown and can be normal or slightly increased. Electromyography (EMG), which involves needle testing of muscle activity, can point to a myopathy without being specific for MTM. Muscle biopsy is diagnostic, whereby a piece of muscle from the thigh or arm is taken and studied under the microscope to highlight the typical central plump nuclei in muscle fibers. The diagnosis depends on demonstrating a large number of muscle fibers with centrally placed nuclei. In X-linked

MTM, all muscles are equally affected and about 50%–80% of the muscle fibers are abnormal. Muscle biopsy can detect 50%–70% of female carriers of X-linked MTM, but the biopsy can also be normal.

Genetic testing can be done in specialized laboratories to detect the common types of myotubularin gene mutations. If no mutation is found on the X chromosome, this means that either the mutation is transmitted autosomally or that it is a mutation that cannot be detected by currently available methods. The mother of a child with X-linked MTM can be tested genetically to see if she is a carrier, as this helps predict the chances of recurrence in a future pregnancy. Testing for X-linked MTM is available on a commercial basis, but testing for autosomal forms is only available through a research study.

Prenatal diagnosis is possible for detecting X-linked MTM by tracing the family history of the disease by a process of linkage analysis, which works only if there is more than one affected male member in the family. This can be done even if the exact type of genetic mutation is not known. Pre-implantation genetic diagnosis (PGD) is a technique whereby testing is done on the embryo and only unaffected embryos are placed back in the uterus for continuation of pregnancy.

Treatment and management

There is no proven treatment to cure or stop progression of MTM, but aggressive supportive measures for swallowing and breathing are warranted to preserve good functional ability, as these have been shown to prolong life expectancy. A team approach, including a neurologist, pulmonologist, orthopedic surgeon, physiatrist, physical therapist, occupational therapist, and geneticist, ensures the best possible therapy.

Tracheostomy tubes and ventilators help with breathing. In some cases, the muscles become stronger with time, and the tubes can be removed. Stents can be used to widen and support floppy airways. Lung infections can be treated with antibiotics. Chest physiotherapy helps to periodically clear lung secretions and decrease the incidence of pneumonia. Nutrients can be fed via oral feeding tubes and G-tubes. There are no special ingredients to be incorporated in the diet, as no supplement has been consistently proven to improve muscle strength and build muscle bulk. Caloric intake should be tailored to the requirements of each individual child.

Physical therapy plays a very important part in maintaining and improving muscle strength, joint flexibility, range of motion, and gait. Care should be taken not to overexert and fatigue the already weak muscles, and a regular exercise program should be devised. Passive stretching, bracing, and surgical-release procedures are

QUESTIONS TO ASK YOUR DOCTOR

- What support for myotubular myopathy can be provided to my child?
- If a genetic disorder seems to run in my family, what are the chances that future children will have this disorder?
- Is genetic testing available to determine my and my partner's genetic carrier status?
- Can it be determined if a current pregnancy has myotubular myopathy?

done to prevent tendon and joint contractures. Bracing or surgery may be needed to correct spinal deformities. The occupational therapist can help in devising adaptive equipment for walking and for other daily activities.

Speech therapy is important to overcome problems with speaking due to poor phonation and articulation. Passy-Muir speaking valves can be used in patients who have a tracheostomy tube. Orthodontic services are needed to correct dental malocclusion. Some children can learn to communicate using sign language, communication assist devices, or high-tech computerized devices. Intelligence is not affected, and therefore these children may even be able to attend regular schools. Artificial tears should be used to prevent dry eyes. Yearly blood tests and liver function tests should be done to monitor the development of anemia and liver malfunction. Folic acid is used when the child has anemia and spherical red blood cells. Appropriate precautions should be taken to avoid bleeding during any major surgery.

Genetic counseling should be sought after a child has been diagnosed with MTM to discuss the prognosis for the child, to help the couple with future reproductive planning, and to help with prenatal diagnosis. The probability of having another affected child varies with the specific mode of inheritance.

Prognosis

Only males are severely affected by X-linked MTM, and prognosis has been historically poor due to early respiratory failure. The children lack enough strength and endurance in the respiratory muscles to withstand respiratory complications such as infections and lung collapse. Death used to occur within one to two years of life, with a mean of five months. Respiratory weakness and frequent pneumonias indicate poor prognosis. Today, with interventions like ventilators and tracheostomy tubes, these complications are

delayed and survival is prolonged. Currently, more than two-thirds of children with MTM survive past the first year of life. In X-linked MTM, contrary to prior thinking, the muscle weakness does not appear to be progressive. Children with autosomal recessive MTM usually survive past infancy. Those with autosomal dominant MTM even survive into late adulthood, and the disease is compatible with a normal life expectancy.

Nail-patella syndrome

Definition

Nail-patella syndrome is a genetic disease of the connective tissue that produces defects in the fingernails, knee caps, and kidneys.

Description

Nail-patella syndrome is also known as Fong disease, Hereditary Onycho-Osteodysplasia (H.O.O.D.), Iliac Horn Disease, and Turner-Kieser syndrome. Patients who have nail-patella syndrome may show a variety of physical abnormalities. The hallmark features of this syndrome are poorly developed fingernails, toenails, and patellae (kneecaps). Other common abnormalities include elbow deformities, abnormally shaped pelvis bone (hip bone), and kidney (renal) disease.

Less common medical findings include changes in the upper lip, the roof of the mouth, and unusual skeletal abnormalities. Skeletal abnormalities may include poorly developed scapulae (shoulder blades), sideways bent fingers (clinodactyly), clubfoot, scoliosis, and unusual neck bones. There are also other effects, such as thickening of the basement membrane in the skin and of the tiny clusters of capillaries (glomeruli) in the kidney. Scientists have recognized an association between nail-patella syndrome and colon cancer. Nail-patella syndrome is associated with open-angle glaucoma, which, if untreated, may lead to blindness. Patients may also have cataracts, drooping eyelids (ptosis), or corneal problems such as glaucoma.

People with nail-patella syndrome may display only a few or many of the recognized signs of this disease. Symptoms vary widely from person to person. Signs even vary within a single family with multiple affected members.

Genetic profile

Nail-patella syndrome has been recognized as an inherited disorder for over 100 years. It is caused by

mutations in a gene known as LIM homeobox transcription factor 1-beta (*LMX1B*), located on the long arm of chromosome 9.

The *LMX1B* gene codes for a protein that is important in organizing embryonic limb development. Mutations in this gene have been detected in many unrelated people with nail-patella syndrome. Scientists have also been able to interrupt this gene in mice to produce defects similar to those seen in human nail-patella syndrome.

Nail-patella syndrome is inherited in an autosomal dominant manner. This means that possession of only one copy of the defective gene is enough to cause disease. When a parent has nail-patella syndrome, each of their children has a 50% chance to inherit the disease-causing mutation.

Diagram of two legs affected by nail-patella syndrome. Note the absence of the patella in this image of knees. (Gale)

A new mutation causing nail-patella syndrome can occur in a person with no family history. This is called a sporadic occurrence and accounts for approximately 20% of cases of nail-patella syndrome. The children of a person with sporadic nail-patella syndrome are at a 50% risk of developing signs of the disorder.

Demographics

The incidence of nail-patella syndrome is approximately 1 in 50,000 births. This disorder affects males and females equally. It is found throughout the world and occurs in all ethnic groups. The strongest risk factor for nail-patella syndrome is a family history of the disease.

Signs and symptoms

Medical signs of nail-patella syndrome vary widely between patients. Some patients with this disorder do not display symptoms. These patients are discovered to have nail-patella syndrome only when genetic studies trace their family history. Scientists are now working to learn what causes different people to display such different symptoms of nail-patella syndrome.

The most obvious signs associated with nail-patella syndrome is absent, poorly developed, or unusual fingernails. Fingernail abnormalities are found in over 80% of patients with this disorder. Abnormalities may be found in one or more fingernails. Only rarely are all fingernails affected. This disease most commonly affects the fingernails of the thumbs and index fingers. The pinky fingernail is least likely to be affected. Fingernails may be small and concave with pitting, ridges, splits, and/or discoloration. Toenails are less often affected. The lunulae, or light-colored crescent moons, at the base of the fingernail bed next to the cuticle are sometimes triangular-shaped in people with nail-patella syndrome.

Kneecap abnormalities are the second most common sign associated with this disorder. Either or both kneecaps may be missing or poorly formed. If present, kneecaps are likely to be dislocated. The knees of people with nail-patella syndrome may have a square appearance. Besides the kneecap, other support structures including bones, ligaments, and tendons may be malformed. These support structures stabilize the knee, therefore patients with some leg malformations may have difficulty in walking.

The hip bones of approximately 80% of patients with nail-patella syndrome have unusual bony projections called posterior iliac horns. These bony projections, or spurs, are internal and not obvious unless they are detected on x-ray. This unusual pelvic anatomy is not associated with any other disease.

KEY TERMS

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted either through the mother's vagina or abdominal wall and a sample of cells is collected from around the early fetus. These cells are then tested for chromosome abnormalities or other genetic diseases.

Glomeruli—Tiny clusters of capillaries in the kidney.

Hematuria—The presence of blood in the urine.

Patella—The kneecap.

Proteinuria—Excess protein in the urine.

Kidney disease is present in 30% to 50% of people with nail-patella syndrome. Biopsy shows lesions that resemble those of inflammation of the clusters of capillaries in the kidneys (glomerulonephritis) but without any infection present. Kidney failure is the most dangerous consequence of nail-patella syndrome. It occurs in about 30% of patients who have kidney involvement. An early sign of kidney involvement is the presence of protein or blood in the urine (chronic, benign proteinuria and hematuria). Kidney involvement is progressive, so early diagnosis and treatment of renal disease is important. Kidney disease has been reported in children with nail-patella syndrome, but renal involvement more commonly develops during adulthood.

Various skeletal symptoms may occur. Patients with nail-patella syndrome may not be able to fully straighten their arms at the elbow. This may create a webbed appearance at the elbow joint. Patients may have sideways bent fingers, poorly developed shoulder blades, clubfoot, hip dislocation, unusual neck bones, or scoliosis.

Eye problems may be present and vary from person to person. Nail-patella syndrome is associated with open angle glaucoma. Open angle glaucoma is caused by fluid blocked into the front chamber of the eye. This blocked fluid builds increasing pressure into the eye. If untreated, this increased pressure may lead to permanent damage of the optic nerve and irreversible blindness. Some patients with nail-patella syndrome have ptosis, or drooping eyelids. Nail-patella syndrome has also been associated with abnormalities of the cornea, cataracts, and astigmatism. Additionally, the irises of the eye may be multicolored, possibly displaying a clover-shaped pattern of color.

QUESTIONS TO ASK YOUR DOCTOR

- On what basis does a physician diagnose a person with nail-patella syndrome?
- Is nail-patella a life-threatening condition, and if not, what are its most serious medical consequences?
- Should my child be monitored on an ongoing basis for his nail-patella syndrome, and if so, what tests are recommended?

Diagnosis

Genetic testing for nail-patella syndrome is available only through research institutions that are working to further characterize this disorder. Genetic testing cannot predict which signs of the disease will develop, nor can genetic testing predict the severity of disease symptoms. Improved genetic testing for nail-patella syndrome is anticipated in the future.

Diagnosis of this disease is most often made on visual medical clues such as the characteristic abnormalities of the fingernails and kneecaps. Diagnosis is confirmed by x-ray images of the affected bones and, when indicated, kidney biopsy. The bony pelvic spurs found in 80% of patients with nail-patella syndrome are not associated with any other disease.

Prenatal diagnosis for nail-patella syndrome by third-trimester ultrasound was first documented in 1998. Prenatal diagnosis via genetic testing of cells obtained by chorionic villus sampling was first reported the same year. Prenatal genetic testing for nail-patella syndrome is not yet widely available. There is controversy surrounding the use of prenatal testing for such a variable disorder. Prenatal testing cannot predict the extent of an individual's disease.

Treatment and management

Treatment is usually not necessary. Treatment, when required, depends on each patient's specific symptoms. Severe kidney disease is treated with dialysis or a kidney transplant. Patients receiving kidney transplant do not develop nail-patella type renal complications in their new kidney.

A wheelchair may be required if walking becomes painful due to bone, tendon, ligament, or muscle defects. Orthopedic surgery may be necessary for congenital club-foot deformity. Manipulation or surgery may be required

to correct hip dislocation. Cataracts are also surgically treated. Medical treatment at early signs of glaucoma prevents progression of the disease to blindness.

Genetic counseling is offered to persons who have the disease. Parents with this disease have a 50% chance of passing it to each of their children. Current genetic testing technology cannot predict the severity or scope of an individual's symptoms.

Because many possible manifestations of nail-patella syndrome exist, patients are advised to pursue extra medical care including regular urinalysis and special eye exams. Children with nail-patella syndrome should be screened for scoliosis.

Prognosis

Survival among patients with nail-patella syndrome is not decreased unless they exhibit renal complications. It is estimated that 8% of individuals with nail-patella syndrome who seek medical attention eventually die of kidney disease.

Nance-Insley syndrome

Definition

Nance-Insley syndrome is a craniofacial anomaly that is caused by a gene mutation interfering with prenatal bone development. The observable results are a short physique, flattened face, and overgrowth at joints. Another name for this condition is otospondylomegaepiphyseal dysplasia, derived from the Greek words “oto” (referring to the eyes), “spondylos” (referring to the spine), and “epiphyseal” (referring to the formative areas of the bones). The Greek word “dysplasia” refers to abnormal tissue formation. Nance-Insley is related to Stickler syndrome but is distinct from it. Nance-Insley is more severe in shared symptoms and involves hearing disabilities instead of the visual disability of Stickler.

Description

This disorder is caused by a mutation on the gene *COL11A2* responsible for producing collagen XI, an organic gel that influences the development of bones and cartilage in the skeletal system. People with Nance-Insley are affected mostly in their bone development and structure. The distinct facial features are due to weak bone structures under the face. There is no effect on intellectual function.

The distinct facial features of an affected person include an abnormally small lower jaw and an underdeveloped midface. The underdeveloped midface is noted by a small nose and flat nasal bridge. In addition to the facial features, the most notable feature of Nance-Insley is the relatively short stature of those affected. Other observable features include an abnormal skeletal framework and wide-set eyes. Almost all affected individuals have a cleft palate.

Expected characteristics include the following:

- Shortened limbs
- Short hands and feet
- Enlarged joints
- Flattened vertebrae
- Early onset of arthritis
- Hearing loss
- Joint pain
- Uprturned nose

Some of the common problems throughout the lifespan include pain in the joints and continually diminishing hearing. Many people with Nance-Insley syndrome suffer from the early onset of osteoarthritis.

KEY TERMS

Cartilage—The stiff yet flexible connective tissue found in many areas in the body, which grows and repairs more slowly than other connective tissue.

Fluorescence in-situ hybridization (FISH)—A method of analyzing the structures of human genetics that uses fluorescent probes designed to link to specific genetic particles such as proteins, genes, or chromosomal material.

Osteoarthritis—A group of diseases and mechanical abnormalities involving degradation of joints.

Type XI collagen—A type of collagen that produces an organic gel that helps cartilage to convert into bone and helps bone growth in the developing fetus.

Genetic profile

Nance-Insley syndrome is caused by a mutation on the gene *COL11A2* on chromosome 6. This gene is responsible for production of the type XI collagen. This collagen produces an organic gel that contributes to the systematic conversion of cartilage into bone and the orderly growth of bone in the developing fetus. Without type XI collagen, there is an overgrowth at the end of long bones contributing to stiff, inflexible joints. Another effect of the lack of type XI collagen is a decrease in bone growth.

Demographics

This condition is very rare. There is an extremely limited number of reports in the literature. No prevalence data were available as of 2015. The gene responsible for this disorder has been determined to be autosomal, which means that males and females are equally affected. The trait is dominant in some cases and recessive in others. Some cases have been shown to be due to a sporadic mutation.

Signs and symptoms

A child born with Nance-Insley syndrome will have abnormal bone growth, which is manifested in the characteristic facial features such as a small nose, flat nasal bridge, and underdeveloped midface. Other bone problems include the overgrowth at joints and short limbs. Other symptoms occurring in this syndrome include wide-set eyes, hearing loss, and a cleft palate.

The mutation responsible for Nance-Insley syndrome can be inherited in three manners: as an autosomal

QUESTIONS TO ASK YOUR DOCTOR

- What corrective surgery should I expect?
- How do other people with Nance-Insley cope with daily living skills?
- Is genetic counseling important for my situation?
- What are the chances that a child of mine will be born with Nance-Insley?
- How often should I be physically evaluated?
- Will my condition get worse?

dominant trait; as an autosomal passive trait; and as a spontaneous mutation. In some cases, the trait is dominant, but in another it is recessive, which is strange but not extraordinarily unusual. If a child is born with Nance-Insley syndrome there is a chance that later siblings may have it also and that current siblings are carriers. The age of either parent has been determined to be inconsequential in the development of this disorder.

Diagnosis

Signs of this disorder are observable from birth. However, many of these signs are also symptoms of Stickler syndrome. Identifying this condition as Nance-Insley with its accompanying complications is only possible through a genetic test of a blood sample.

The main test for recognizing chromosomal disorders is the fluorescence in-situ hybridization (FISH). This method of analyzing the structures of human genetics relies on fluorescent probes designed to link to specific genetic particles such as proteins, genes, or chromosomal material. If the correlating probe cannot link to the material for which it is designed, then the result is accepted as an absence of the material. In testing for Nance-Insley syndrome, the probes specific to the *COL11A2* gene on chromosome 6 would be injected into genetic material from the affected person. If examination of the probes does not detect a continuous pattern, then the person definitely has a mutation on this gene.

The condition can also be detected prenatally through amniocentesis. If a parent suspects that he or she is a carrier for Nance-Insley syndrome, an amniocentesis is able to detect the presence of the mutations. However, a test for Nance-Insley syndrome is complicated, so it is not usually done in amniocentesis analysis. The distinct characteristics, observable at birth, are not usually observable through the prenatal ultrasound. The problem with an ultrasound picture of the developing fetus is that

as of 2015, ultrasound was not powerful enough to detect the subtle features that would suggest the child has Nance-Insley syndrome.

Treatment and management

As noted above, the presence of the mutation can be detected through a prenatal test such as amniocentesis. Detecting the mutation is not usually a goal of typical amniocentesis because the condition is so rare. Prenatal counseling is recommended for a couple when one or both are carriers of the mutated gene. Information on this disorder and others that can arise through spontaneous mutations is recommended for parents during pregnancy.

There is no cure for the underlying condition of the mutation. The damage that is done prenatally remains for a lifetime. The various treatments for Nance-Insley syndrome are concerned with alleviating associated disabilities and delaying any perceived deterioration.

Traditional treatment

The usual treatment for children involves continuous evaluations of all related conditions. Orthopedic surgery may be necessary at times. Physical therapy and adaptive devices may help alleviate some of the problems. The cleft palate needs to be repaired in childhood, as well as any condition of the ears. If there is no chance for correcting the problems with the ears, therapy designed to help the patient adapt to a loss of hearing is required.

Some problems are less severe with age. However, joint pain and loss of hearing require assessment and treatment throughout the lifespan. Joint replacement may be required at a relatively young age.

Alternative treatment

The popularity of human growth hormone therapy may lead someone with Nance-Insley to consider it as an acceptable therapy for this condition. However, the short stature of the Nance-Insley patient is due to bone malformations. Such disorders do not respond well to growth hormone therapy.

Prognosis

There is no cure for Nance-Insley syndrome. Some of the initial bone structure problems may be alleviated with age. However, the early onset of osteoarthritis is fairly certain, as is lifetime hearing problems. Those affected with this syndrome have intellectual skills in the normal range and can learn adaptive skills well. Also, there is nothing inherent in this disorder to suggest less than average life expectancy.

Narcolepsy

Definition

Narcolepsy is a lifelong disorder marked by excessive daytime sleepiness, uncontrollable sleep attacks, and interrupted nighttime sleep. There are two types of Narcolepsy: Type 1 (NT1) and Type 2 (NT2). Both types share many of the same symptoms. One major difference is that people with NT1 have cataplexy, while people with NT2 do not. Cataplexy is a sudden loss of muscle tone, that can last up to 30 minutes. Individuals with NT1 also have a dramatic decrease in the neuro-hormone hypocretin (orexin), which regulates sleep/wake cycles and eating behavior. Individuals with NT2, on the other hand, have normal levels.

Description

Narcolepsy usually starts in adolescence, but it can have an onset in childhood. It is the second-leading cause of excessive daytime sleepiness after obstructive sleep

Narcolepsy causes affected individuals to suddenly fall into a deep sleep, even in the middle of an activity. (A and N photography/Shutterstock)

apnea. People with narcolepsy suffer from sleep attacks in which they unwillingly fall asleep during their daily activities. Sleep attacks can last from a few seconds to more than an hour. Depending on where they occur, they may be mildly inconvenient or even dangerous. Contrary to what one may think, individuals with a narcolepsy disorder do not get more sleep than those without narcolepsy.

Narcolepsy also affects nighttime sleep. Most people with narcolepsy are unable to sleep more than a couple of hours at night. They may experience hallucinations when falling asleep and waking up and vivid dreams that cause them to move around excessively and talk in their sleep. It is also common for them to become paralyzed when falling asleep or waking up. Narcolepsy can affect rapid eye movement (REM) sleep. Our brain is the most active during REM sleep, and this is when dreams usually occur. People with narcolepsy often go directly into REM sleep. Healthy people, on the other hand, usually first have 90 minutes of non-REM sleep which is followed by REM sleep. People with narcolepsy can also experience REM sleep throughout the day.

People with Type 1 Narcolepsy (NT1) can experience cataplexy, where they have a sudden weakness of their muscles. This weakness can cause them to collapse or fall, which can sometimes result in injury. Cataplexy can be triggered by emotions like laughter, surprise, or anger.

Genetic profile

Narcolepsy is a complex disease caused by both genetic and environmental risk factors. It is likely that narcolepsy has different causes in different individuals. The disorder sometimes runs in families, but most people with narcolepsy have no relatives with the disorder. Both

identical twins have narcolepsy in about one in four (25%) cases. This suggests that, in many cases, environmental factors play a role in triggering the disorder. More is known about the genetics of NT1 than NT2.

Immune System Genes

Most of the genetic variations known to be associated with NT1 are related to the immune system. Across ethnicities, 88% to 98% of patients affected by NT1 share the HLA type *HLA-DQB1*0602*. The *HLA* gene family provides instructions for making a group of proteins known as the human leukocyte antigen (HLA) complex, which helps the immune system distinguish the body's own proteins from proteins made by foreign invaders such as viruses and bacteria.

It is likely that narcolepsy has an autoimmune component. Autoimmune reactions happen when the immune system attacks the body by mistake. NT1 may result from an autoimmune reaction in individuals with a susceptible HLA type that is triggered by infections. A number of lines of evidence support this theory:

- The onset of NT1 is often in the late spring, which suggests that it might be triggered by infections in the winter.
- NT1 has been associated with streptococcus infections.
- An increased risk of NT1 is associated with the H1N1 vaccine, Pandemrix.
- An increased risk of NT1 was found in children with the HLA type *HLA-DQB1*0602* following the H1N1 2009-2010 pandemic.

Orexin deficiency

Orexin is undetectable in the cerebrospinal fluid (CSF) of approximately 90% of patients with NT1. This protein is produced by the nerve cells (neurons) and regulates sleep/wake cycles and eating behavior. There has been one, early onset, severe case of NT1 that was associated with a variation (mutation) in the orexin gene. Most cases, are not caused by variations in that gene. It is possible that in some cases, NT1 is caused by the loss of the neurons that produce orexin. This might happen as the result of an autoimmune reaction where the body attacks the orexin producing neurons. This process, in turn, reduces, or even eliminates, orexin in the CSF.

Other genes.

Several additional gene loci have been identified to be associated with the development of narcolepsy, including the *TRAC*, *TNFSF4*, *CTSH*, *P2RY11*, *EIF3G*, *ZNF365*, *TCRB*, *IL10RB-IFNAR1*, and *CCR1/CCR3* gene loci.

KEY TERMS

Agonist—A chemical or biological agent that binds to a receptor and activates the receptor to produce a biological response.

Autoimmune reaction—When the body attacks itself, thinking it is being invaded by a foreign body like a bacteria.

Cataplexy—A symptom of narcolepsy in which there is a sudden episode of muscle weakness triggered by emotions. The muscle weakness may cause the person's knees to buckle, or the head to drop. In severe cases, the patient may become paralyzed for a few seconds to a few minutes.

Hypnagogic hallucinations—Dream-like auditory or visual hallucinations that occur while falling asleep.

Hypocretin—A neuro-hormone involved in the regulation of sleep, wakefulness, and eating behaviors, also known as orexin.

Hypothalamus—A part of the forebrain that controls heartbeat, thirst, hunger, body temperature and pressure, blood sugar levels, and other functions.

Sleep paralysis—An abnormal episode of sleep in which the patient cannot move for a few minutes, usually occurring on falling asleep or waking up. Often found in patients with narcolepsy.

Demographics

According to the National Institute for Neurological Disorders and Stroke (NINDS), narcolepsy is an under-recognized and under-diagnosed condition in the United States. The disorder occurs worldwide in every racial and ethnic group, affecting males and females equally. The prevalence of NT1 is 0.03%–0.05% as determined by several population studies conducted across the world. The prevalence of NT2 is approximately 36% lower than NT1. First-degree relatives (e.g., children, parents and siblings) of people with NT1 have approximately a 10- to 40-fold increased risk of narcolepsy. The age of onset is typically 10 to 20 years.

Signs and symptoms

While the symptoms of narcolepsy usually appear during adolescence, they can occur at any age, and the disease might not be diagnosed for many years. It is not progressive, and it is not fatal, but it is chronic. Most often, the first symptom is an overwhelming feeling of

QUESTIONS TO ASK YOUR DOCTOR

- Are my symptoms of sleepiness caused by narcolepsy?
- How will you determine whether I have narcolepsy?
- Will my symptoms get worse, and are there other symptoms that I could develop?
- What treatments are available for my symptoms, and what interactions could occur with medications I already take?
- Are there nonpharmacological approaches I can use to treat the symptoms of narcolepsy?
- Are there certain activities I should avoid?
- How can I keep others and myself safe if I have a sudden sleep attack or muscle weakness?

fatigue. After several months or years, cataplexy and other symptoms may appear.

Cataplexy is the most dramatic symptom of narcolepsy. It affects 75% of people with the disorder. During attacks, the loss of muscle control can range from a weak response, including buckling of the knees or neck muscles going slack, to severe, such as a complete body collapse. This loss of muscle tone is temporary, lasting from a few seconds to half an hour, but it is frightening. The attacks can occur at any time but are often triggered by strong emotions, such as anger, joy, or surprise.

Other symptoms of narcolepsy include the following:

- Sleep attacks: short, uncontrollable sleep episodes throughout the day
- Sleep paralysis: a frightening inability to move shortly after awakening or dozing off
- Auditory or visual hallucinations: intense, sometimes terrifying experiences at the beginning or end of a sleep period
- Disturbed nighttime sleep: tossing and turning, nightmares, and frequent awakenings during the night

Diagnosis

Narcolepsy is a complex disorder, and it is often misdiagnosed. It takes 14 years, on average, for an individual to be correctly diagnosed. If a person experiences both excessive daytime sleepiness and cataplexy, a diagnosis of NT1 may be made on patient history alone. Laboratory

tests, however, can confirm a diagnosis. They may include an overnight polysomnogram—a test in which sleep is monitored with electrocardiography, video, and respiratory parameters. A Multiple Sleep Latency Test, which measures sleep latency (onset) and how quickly REM sleep occurs, may be used. People who have narcolepsy usually fall asleep in less than five minutes. The absence of orexin in the cerebrospinal fluid can help confirm a diagnosis of NT1.

NT2 is more difficult to diagnose. It is suspected in patients who do not have cataplexy, have normal orexin levels in their CSF, and who have two or more abnormal sleep onset REM periods during a sleep test.

Treatment and management

There is no cure for narcolepsy. The symptoms can be managed with medication or lifestyle adjustment. Amphetamine-like stimulant drugs are often prescribed to control drowsiness and sleep attacks. Patients who do not like taking high doses of stimulants may choose to take smaller doses and “manage” their lifestyles, such as by napping every couple of hours to relieve daytime sleepiness. Antidepressants are often effective in treating symptoms of abnormal REM sleep. Sodium oxybate is a liquid medication that can help treat daytime sleepiness and cataplexy. It is taken before bedtime and two to four hours later.

Approximately 20% of patients with NT1 have abnormally low levels of acylcarnitine. Acylcarnitine is involved in regulating sugar and fat metabolism. Treating with L-carnitine seems to reduce the symptoms of narcolepsy in some people with NT1 and NT2.

Researchers are investigating novel therapies such as orexin replacement therapy, agonists of the hypocretin receptor, and even gene therapy for treatment and prevention of narcolepsy.

Prognosis

Narcolepsy is not a degenerative disease, and patients do not develop other neurologic symptoms. However, narcolepsy can interfere with a person's ability to work, play, drive, and perform other daily activities. In severe cases, the disorder prevents people from living a normal life, leading to depression and a loss of independence.

Nephrogenic diabetes insipidus

Definition

Nephrogenic diabetes insipidus (NDI) is a kidney disorder characterized by the organ's inability to respond to the antidiuretic hormone (ADH), also called arginine vasopressin (AVP), produced in the hypothalamus, a structure of the brain. NDI involves an abnormality in the kidney tubules that prevents the proper amount of water from being reabsorbed from the kidneys back into the body. Instead, the water is excreted in large amounts as diluted urine.

Description

There are two categories of nephrogenic diabetes insipidus: inherited and acquired. Within the inherited

group, there are three types of NDI: X-linked, autosomal recessive, and autosomal dominant. Unlike the more common diabetic disorder diabetes mellitus, NDI is not related to insulin production or levels of sugar in the blood and urine.

Ninety percent of inherited NDI is X-linked, meaning it is caused by an alteration in a gene carried on the X chromosome. Since women have two X chromosomes and men have only one, an X-linked recessive condition is expected to affect men since they do not have a second X chromosome with a normal copy of the gene to produce the needed substance. Autosomal recessive NDI is rarer and equally affects males and females. Autosomal dominant NDI is the rarest of the three and affects both males and females.

Inherited NDI is present from birth, and symptoms usually manifest within the first several days of life. If the disorder is not diagnosed and treated early, it will cause the body to lose too much water. This dehydration can lead to brain damage and eventually death. With early diagnosis and treatment to avoid severe dehydration, however, the person can live a normal lifespan without any mental impairment.

Acquired NDI is the most common type of the disease and can be acquired at any age. It is most frequently acquired through the long-term use of certain prescription medicines, including demeclocycline, methicillin, foscarnet, and some anticancer drugs. In rare instances, it can be caused by an underlying disease or disorder, such as sickle cell anemia, chronic kidney failure, sarcoidosis, amyloidosis, Fanconi syndrome, and Sjögren's syndrome. Other rare causes of acquired NDI are low blood levels of potassium and abnormally high blood calcium levels. Pregnancy can also result in temporary acquired NDI. However, most cases of acquired NDI are caused by long-term use of the prescription drug lithium, which is used to treat bipolar disorder (manic depression).

NDI, also called gypsy's curse, is caused by the kidneys' inability to respond to the water-saving hormone (ADH), a natural chemical that is manufactured in the brain but that works in the kidneys. The body's two kidneys make urine, which is then sent to the bladder, and help to maintain the balance of water, salt, and minerals. A majority of the water is reabsorbed from nephrons in the kidneys into surrounding inner tissue. Each kidney contains hundreds of thousands of nephrons, microscopic tubes that filter the water flowing into the kidneys. The water that is not absorbed becomes urine.

The first references to NDI appeared in medical literature in the 1880s, but it wasn't until the 1940s that

detailed observations and studies were done. In a landmark 1946 study published in the *American Journal of the Diseases of Children*, authors A. J. Waring, L. Kajdi, and V. Tappan summarized the main clinical and pathophysiological aspects of the disorder. “The presenting complaints were unexplained fever, failure to gain weight, and constipation. The bouts of dehydration are usually not associated with acidosis. The thirst of one of the patients studied was satisfied only when five to six times the normal requirement of fluid was offered. The levels of (blood) serum sodium and chloride decreased to normal and the infant remained free from fever on this high fluid intake.”

Genetic profile

Genes are the blueprint for the human body and direct the development of cells and tissue. Mutations in some genes can cause genetic disorders such as inherited nephrogenic diabetes insipidus. Every cell in the body has 23 pairs of chromosomes, 22 pairs of which are called autosomes and contain two copies of individual genes. The chromosomes in the 23rd pair are called the sex chromosomes because they determine a person’s sex. Men have an X and a Y chromosome, while women have two X chromosomes. X-linked nephrogenic diabetes insipidus is caused by a defect in the vasopressin-2 receptor (*AVPR2*) gene in the X chromosome that renders the kidneys unresponsive to ADH.

Since inherited NDI is usually inherited as an X-linked condition, almost all persons with the disorder are male. Females have two X chromosomes, which means they have two copies of each gene. Males have only one X chromosome and one copy of each gene. If a male has an altered *AVPR2* gene, he will have NDI. If a female has one altered gene, she will be a carrier and will be at risk to pass the altered gene on to her children. If her son inherits the altered gene, he will be affected. If her daughter inherits the affected gene, she will be a carrier like her mother. If her son does not inherit the altered gene, he will not be affected and will not pass the altered gene on to his children. If a daughter does not inherit the altered gene, she will not pass it on to her children. If an affected male has children, all of his daughters will be carriers but none of his sons will be affected.

Women who have the abnormal *AVPR2* gene may have milder symptoms of NDI than males. This is because early in development, one X-chromosome in each cell of a female is “turned off” at random. If by chance a woman has more than half of the X chromosomes that carry the normal *AVPR2* gene turned off, she

may have mild symptoms of NDI. Approximately 90% of people with inherited NDI have it as a result of this X-linked gene.

The gene that produces aquaporin-2 (*AQP2*) can cause autosomal recessive and autosomal dominant NDI when altered. The *AQP2* gene produces a protein that helps the kidneys reabsorb water into the body and concentrate urine. Since the *AQP2* gene is carried on chromosome 12, a nonsex chromosome, it is carried in both males and females. Also, an abnormal *AQP2* gene is recessive, meaning that if only one of the person’s two *AQP2* genes is abnormal, it will not cause NDI. If both genes are abnormal, then that person will have NDI. A child born to parents who are both carriers of autosomal recessive NDI has a 25% chance to be affected since the child is at risk to receive a copy of the altered gene from his or her mother and father. In autosomal dominant NDI, either parent may be affected and may pass the altered gene to the child. Also, only one altered gene is necessary to be present for the condition to manifest. Acquired NDI is not hereditary and cannot be genetically passed on from parents to their offspring.

Demographics

In general, the various types of NDI appear to affect people regardless of age, race, or ethnicity. However, in X-linked NDI, the predominance of cases is among males. The exact number of people with NDI is not known. Estimates range from 1 in every 500,000 to 5 in every 100,000. In acquired NDI, one of the diseases that can cause it is sickle cell anemia, which occurs primarily in people of African descent.

Signs and symptoms

The primary symptoms for all types of NDI are generally the same: polyuria (excreting large amounts of dilute urine) and polydipsia, drinking excessive amounts of water, from 3–10 gal (12–38 L) per day. In infants born with NDI, symptoms begin to occur within a few days after birth. However, since a child cannot verbally communicate its need for greater than normal amounts of water, parents, physicians, and other caregivers must be alert to other signs of the disorder. Overt signs include fever, irritability, and constipation, all of which may indicate dehydration. The child may also vomit often, be anorexic, and prefer water to milk. Other signs include rapid and severe dehydration if fluids are restricted or withheld, high levels of sodium and chloride in the blood, and urine that does not have a high specific gravity.

KEY TERMS

Acidosis—A condition of decreased alkalinity resulting from abnormally high acid levels (low pH) in the blood and tissues. Usually indicated by sickly sweet breath, headaches, nausea, vomiting, and visual impairments.

Alzheimer's disease—A degenerative disease of the central nervous system characterized by premature senility and other mental deterioration.

Amyloidosis—Accumulation of amyloid deposits in various organs and tissues in the body such that normal functioning of an organ is compromised.

Dehydration—An extreme loss of water in the body, which, if untreated, can lead to brain damage and death.

Electrolyte—A solution or a substance in a solution consisting of various chemicals that can carry electric charges. Electrolytes exist in the blood as acids, bases, and salts, such as sodium, calcium, potassium, chlorine, and magnesium.

Fanconi syndrome—A reabsorption disorder in the kidney tubules.

Kidney tubules—A portion of the kidneys that causes water to be excreted as urine or reabsorbed into the body.

Nephrons—Microscopic tubes that filter the water that flows into the kidneys.

Osmolarity—The concentration of an osmotic solution, especially when measured in osmoles or milliosmoles per liter of solution.

Osmotically—Referring to the movement of a solvent through a semipermeable membrane (as of a living cell) into a solution of higher solute concentration that tends to equalize the concentrations of solute on the two sides of the membrane.

Sarcoidosis—A chronic disease characterized by nodules forming in the lymph nodes, lungs, bones, and skin.

Sickle cell anemia—A chronic, inherited blood disorder characterized by sickle-shaped red blood cells. It occurs primarily in people of African descent and produces symptoms including episodic pain in the joints, fever, leg ulcers, and jaundice.

Sjögren's syndrome—A chronic inflammatory disease often associated with rheumatoid arthritis.

Elderly people, usually those with acquired NDI, may need close monitoring for symptoms, especially if they are unable to communicate their need for a large amount of water, such as patients with Alzheimer's disease or other mental deterioration. Also, elderly persons may be less sensitive to their need for water. Because of this, elderly persons with NDI can be more prone to dehydration, leading to such problems as infection, kidney failure, confusion, lethargy, and constipation.

For acquired NDI, close medical monitoring should be done for people at high risk for the disorder. These include people undergoing long-term treatment with lithium and people with sickle cell anemia, chronic kidney failure, other kidney problems, very low blood levels of potassium and protein, and high blood levels of calcium.

Diagnosis

NDI is one of four types of diabetes insipidus (DI). In all four types, the basic symptoms are extreme thirst and excessive urination. Depending on other symptoms and conditions present in the patient, it can often be easy

for a physician to suspect NDI. However, additional tests are required to confirm it. These include a test of urine concentration to measure the ratio of osmotically active particles (such as sodium) to body water, a blood test to determine plasma concentrations, measuring urine volume, and a test to determine the level of the antidiuretic hormone AVP in blood plasma.

Sometimes physicians will have the patient take a water deprivation test to help determine the type of NDI present. In this test, the patient goes without water or other liquids for up to six hours. The blood plasma concentrations and urine volume are then measured. Even though a patient with NDI will become dehydrated during this test, the doctor monitors the patient's body weight and blood plasma osmolarity levels to ensure that the patient remains within safe parameters. At the end of the test, the patient is generally diagnosed with NDI if he or she has high levels of osmotically active particles in the blood and low levels of osmotically active particles in the urine.

The patient is also given desmopressin acetate (DDAVP), a synthetic version of AVP, to determine if he or she has a different form of DI called pituitary

QUESTIONS TO ASK YOUR DOCTOR

- Please describe the internal body changes that take place in a child with nephrogenic diabetes insipidus.
- What information about this disorder can a genetic counselor provide?
- Are there medications, tests, or other procedures that should be considered when treating a child with nephrogenic diabetes insipidus?
- How will nephrogenic diabetes insipidus affect the kind of life my child will be able to live?

diabetes insipidus, also known as central diabetes insipidus. In addition, the physician measures heart rate and diastolic blood pressure to help determine whether the NDI is caused by defective *AVPR2* genes or defective *AQP2* genes.

Treatment and management

Although there is no cure for NDI, all forms of the disorder are treatable. Drinking plenty of water is the first and foremost treatment. Regardless of the age of the patient, water must be available at all times. However, it is important for a child to maintain control of NDI with medication so that he or she can eat, drink, and grow normally.

Medications used to treat NDI include one or a combination of indomethacin (Indocin), amiloride (Mida-mor), the thiazide diuretics hydrochlorothiazide (HydroDIURIL) or chlorothiazide (Diuril), and occasionally desmopressin.

Management of NDI is also accomplished through restricting the intake of sodium and sometimes protein. Thiazide diuretics can reduce a patient's urine output, but they may also cause potassium depletion. Potassium supplements may be required. NDI that occurs during pregnancy usually goes away after delivery of the child. NDI caused by diet abnormalities is usually reversible once the diet becomes balanced. Acquired NDI caused by electrolyte imbalances such as low levels of calcium in the blood plasma or high levels of potassium in the blood plasma can be reversed once the imbalance is corrected.

In patients with lithium-induced NDI, thiazide diuretics are used cautiously since they reduce the kidneys' ability to excrete lithium. In many, but not all, cases,

people with lithium-induced NDI can improve when the dosage is decreased or stopped. In some cases, the lithium-induced NDI is irreversible.

Prognosis

Infants and children with inherited NDI can live a normal lifespan provided they are diagnosed correctly, treated early, and properly manage the disorder. Without early diagnosis and treatment in infancy, NDI can lead to intellectual disability and even death. Infants and children with NDI tend to be slightly smaller and weigh less than children without NDI. As children with NDI mature into adults, they tend to be slightly shorter than their parents, but with a normal weight. With appropriate treatment and management, NDI should not interfere with activities such as school, work, or sports.

Neu-Laxova syndrome

Definition

Neu-Laxova syndrome (NLS) is a rare disorder characterized by onset of severe growth delay during pregnancy, multiple birth defects, and abnormal physical development of the brain. Affected infants typically die shortly after delivery or are stillborn.

Description

In 1971, Dr. Richard Neu published the first report of a family that included three children with a unique pattern of multiple birth defects. Each child had an unusually small head (microcephaly) and abnormalities of the arms, legs, skin, and external genitalia. The two affected daughters were each stillborn, while the affected son only lived for seven weeks. In 1972, Dr. Renata Laxova described a different family whose children had birth defects similar to those first described by Dr. Neu. The parents in this second family were first cousins to one another. Taken together, these two families were considered evidence of a previously unrecognized genetic syndrome. The disorder was named Neu-Laxova syndrome in honor of these two physicians.

NLS has since become known as a rare, lethal inherited condition characterized by a specific pattern of facial, brain, and limb abnormalities. Other associated abnormalities often include dry, scaly skin; generalized swelling of body tissues (edema); and extremely slow growth.

Genetic profile

NLS is inherited as an autosomal recessive condition. Males and females are equally likely to be affected. It has been reported in a variety of ethnic groups. Proof of autosomal recessive inheritance includes the birth of more than one affected child to normal parents and the observed incidence of infants with NLS among the children of two blood relatives. Consanguinity, or the mating of two biologically related individuals, increases the possibility of having a child with a genetic disorder. Since any two relatives will share a portion of their genes in common, they are more likely to each be a carrier of the same autosomal recessive gene.

In order to be affected with NLS, an individual must inherit two copies of the *NLS* gene or one copy from each carrier parent. A carrier has one *NLS* gene and one normal gene; as such, an NLS carrier appears completely normal. However, two carriers face a risk of 25%, or a 1 in 4 chance, of having a child with NLS. Conversely, they also have a 75% chance of having an unaffected child. These risks apply to each of their pregnancies together.

KEY TERMS

Agenesis of the corpus callosum—Failure of the corpus callosum to form and develop. The corpus callosum is the band of nerve fibers located between the two sides, or hemispheres, of the brain.

Cataract—A clouding of the eye lens or its surrounding membrane that obstructs the passage of light, resulting in blurry vision. Surgery may be performed to remove the cataract.

Cerebellum—A portion of the brain consisting of two cerebellar hemispheres connected by a narrow vermis. The cerebellum is involved in control of skeletal muscles and plays an important role in the coordination of voluntary muscle movement. It interrelates with other areas of the brain to facilitate a variety of movements, including maintaining proper posture and balance, walking, and running, and fine motor skills, such as writing, dressing, and eating.

Cleft lip—A separation of the upper lip that is present from birth but originates early in fetal development. A cleft lip may appear on one side (unilateral) or both sides (bilateral) and is occasionally accompanied by a cleft palate. Surgery is needed to completely repair cleft lip.

Cleft palate—A congenital malformation in which there is an abnormal opening in the roof of the mouth that allows the nasal passages and the mouth to be improperly connected.

Dandy-Walker malformation—A complex structural abnormality of the brain frequently associated with hydrocephalus, or accumulation of excess fluid in the brain. Abnormalities in other areas of the body may also be present. Individuals with Dandy-Walker malformation have varying degrees of mental handicap or none at all.

Placenta—The organ responsible for oxygen and nutrition exchange between a pregnant mother and her developing baby.

Stillbirth—The birth of a baby who has died sometime during the pregnancy or delivery.

Infants with NLS have also been born to non-consanguineous, or unrelated, couples. Any time a child with NLS is born, the parents must be obligate, or mandatory, carriers of one *NLS* gene. As such, they face an increased risk in future pregnancies together of having another affected child.

The gene for NLS has not yet been identified. Thus, it is not possible to perform direct genetic testing to determine carrier status, confirm a clinical diagnosis, or provide accurate prenatal diagnosis.

Demographics

Adequate data are not available to provide a specific statistic regarding the frequency of NLS. The condition is very rare. As of 2015, about 60 cases of Neu-Laxova syndrome had been reported.

Signs and symptoms

Stillborn or newborn infants with NLS have a characteristic pattern of internal and external abnormalities. Not all affected infants will have all of the features listed, and some anomalies are slightly more common than others.

Infants with Neu-Laxova syndrome often have unusual facial features. Their heads are very small, and their foreheads appear to slant backward. The distance between the eyes is wider than normal (hypertelorism), and the eyes are prominent or bulging. Cataracts may be present. The eyelids are typically absent. The bridge of the nose is wide and slightly flattened. The ears are abnormally shaped. The lower jaw appears recessed as compared to the upper jaw (retrognathia), and the mouth itself is usually open with abnormally thick lips. Cleft lip may be present, with or without cleft palate.

The external features of the head and face are a reflection of severe physical abnormalities of the brain. It is not unusual for an infant with NLS to have an underdeveloped cerebellum or even lissencephaly, a more serious malformation characterized by a smooth brain surface. Normal development of the brain includes an intricate pattern of grooves, or gyri, on its outer surface. A lack of these grooves leads to profound intellectual disability among survivors and an increased frequency of medical complications, such as seizures. Other reported brain malformations include agenesis of the corpus callosum and Dandy-Walker malformation.

A variety of limb abnormalities have also been described in NLS. Affected individuals often have shortened arms and legs that are held out from the body in an unusual, fixed position. This positioning is often referred to as flexion contractures. The fingers and toes may appear underdeveloped (hypoplastic) and/or fused together (syndactyly). The heels of the feet are often rounded (rocker-bottom feet), and the neck is short.

Other abnormalities more common to NLS include markedly limited physical growth. This typically begins during pregnancy and, as such, is referred to as

QUESTIONS TO ASK YOUR DOCTOR

- Can Neu-Laxova syndrome be diagnosed prenatally, and if so, how reliable is that diagnosis?
- What information can a genetic counselor give us about this disorder?
- What medical conditions are typically associated with Neu-Laxova syndrome?
- Can you recommend a source for further information about Neu-Laxova syndrome that will help us understand more about this disorder?

intrauterine growth restriction (IUGR). Edema, or an excessive amount of fluid in the tissues of the body, is a hallmark of NLS. The edema may either be generalized and very severe throughout the body or limited only to the face or scalp. The skin is often extremely dry and scaly, a medical condition called ichthyosis. The lungs are often hypoplastic (underdeveloped), even when delivery occurs at term. The external genitalia are often abnormal, but this is more obvious in males than in females since males typically have a small, underdeveloped penis.

Finally, in addition to IUGR during pregnancy, an excessive volume of amniotic fluid (polyhydramnios) often develops. This is due to a combination of abnormal fluid production and impaired fetal swallowing from the associated nervous system abnormalities. The placenta is also usually abnormal in appearance and function.

Diagnosis

Many infants with NLS have been born into families with no previous history of the disorder and/or ones in which the parents are unrelated. Thus, an exact diagnosis of NLS during pregnancy may be very difficult, particularly for a couple with no apparent risk factors. Direct genetic testing for NLS will not be possible until the responsible gene has been identified. Some non-specific prenatal findings should, however, alert the physician that additional prenatal evaluation is warranted. These include IUGR and polyhydramnios. Both findings often lead to an obvious difference in the size of a pregnant woman's uterus and her estimated weeks of pregnancy. A woman whose fetus has severe IUGR and normal amniotic fluid often appears less pregnant than she actually is. In contrast, a woman with polyhydramnios often appears more pregnant, or larger. A detailed prenatal ultrasound test may be used to obtain pictures of abnormalities of the fetus as well as possible abnormalities of the placenta

whenever there is an apparent discrepancy in a woman's size and her dates.

Two groups have separately reported diagnosis of NLS using ultrasound. However, in both cases, the diagnosis was formally established only after delivery. A number of the physical findings associated with NLS, particularly those involving the face, limbs, and brain, may be apparent following a detailed ultrasound later in pregnancy. In experienced hands and with the knowledge of a previous affected infant, some of these findings may be observed earlier.

In one of the published cases, a diagnosis of NLS was helped by the physical findings of an ultrasound exam at 32 weeks of pregnancy. The fetus was found to have many of the abnormalities associated with NLS. In the second report, ultrasound was used to assess fetal movement patterns at 34 weeks of pregnancy. Abnormal fetal movement is indicative of abnormal brain development. The authors were able to document a lack of normal fetal activity, such as breathing movements, sucking, swallowing, hiccups, and movements of the arms and legs in a fetus diagnosed with NLS after birth.

Accurate diagnosis of this condition is difficult before birth for those couples in which no *NLS* gene has been identified and no family history of NLS is known. While the combination of abnormal physical development and possibly abnormal fetal activity is highly indicative of a severe genetic condition, both would not be specific enough to pinpoint NLS as the cause in all cases. Other genetic syndromes would be under consideration, pending a clinical examination after delivery.

For this reason, a careful physical evaluation after birth is critical in establishing a diagnosis of NLS. For those infants who are stillborn and for those who die after delivery, an autopsy is also helpful in documenting all of the associated internal abnormalities. A precise diagnosis facilitates accurate genetic counseling, including prognosis for an affected child and the risk of recurrence for future pregnancies.

Treatment and management

For those couples who have had a previous child with NLS, serial prenatal ultrasound evaluations should be offered to monitor fetal growth, screen for physical abnormalities, and assess fetal well-being later in pregnancy given the increased risk for stillbirth. Ultrasound diagnosis of any of the structural birth defects associated with NLS in these families should be considered evidence of the disorder. Since some of these findings may not become evident until later in pregnancy, termination of the pregnancy may not be an option for some couples. Plans for the remainder of the pregnancy as well as

delivery can, however, be discussed. Given the serious prognosis associated with NLS, some parents may find a noninterventionist approach during labor and delivery, such as no fetal monitoring or Cesarean section delivery, acceptable. A clinical examination after birth is recommended.

Most infants with NLS have either been stillborn or died very shortly after delivery. However, there is one reported case of an affected Japanese infant who lived for 134 days. Humane medical care is therefore appropriate in survivors, although the prognosis would still be extremely poor.

An autopsy is recommended on all affected infants to document and confirm all of the associated physical abnormalities. While this acts as a way to confirm the diagnosis, it is also a useful way to continue to add to the knowledge about the syndrome and its physical effects.

Prognosis

The number of infants described with NLS is small. However, with the exception of the reported infant who lived 134 days, all affected children have either died before delivery or shortly thereafter. NLS is a serious genetic condition whose anomalies prevent long-term survival.

Neural tube defects

Definition

Neural tube defects are severe birth defects in which there is an opening in the spine or skull that exposes the brain or spinal cord. This exposure can result in damage to the brain or spinal cord.

Description

Neural tube defects are among the most common serious birth defects, and they vary considerably in their severity. Neural tube defects happen during the fourth week of pregnancy, if the soft and bony tissue protecting the spine and brain do not form properly. Openings may occur anywhere in the midline of the head or spine. In some cases, the brain or spinal cord is completely exposed or protected by a tough membrane (meninges) and in other cases covered by skin.

Spina bifida, which results from an opening in the spine, accounts for about two-thirds of all neural tube defects. The spine defect may appear anywhere from the neck to the buttocks. In its most severe form, termed “spinal rachischisis,” the entire spinal canal is open, exposing the spinal cord and nerves. More commonly the defect appears as a localized mass on the back that is covered by skin or by the meninges.

Anencephaly is the second most common neural tube defect and accounts for about one-third of cases. Two major subtypes of anencephaly occur. In the most severe form, all of the skull bones are missing, and the brain is entirely exposed. In the second form, called “meroacrania,” only a part of the skull is missing, and a portion of the brain is exposed.

Encephaloceles are the rarest form of neural tube defects. With encephaloceles, a portion of the skull bone is missing, leaving a bony hole through which the brain and its coverings herniate (protrude). Encephaloceles can occur anywhere from the front top half of the skull to the back of the skull near the neck. Encephaloceles on the back of the skull (occipital) are the most common. As with spina bifida, the severity varies greatly. In its mildest form, an encephalocele may appear as only a small area of faulty skin development, with or without any underlying skull defect. At the severe end of the

KEY TERMS

Embryo—The earliest stage of development of a human infant; used to refer to the first eight weeks of pregnancy. The term “fetus” is used from roughly the third month of pregnancy until delivery.

Hydrocephalus—The excess accumulation of cerebrospinal fluid around the brain that often causes enlargement of the head.

Meninges—The two-layered membrane that covers the brain and spinal cord.

Midline—An imaginary line that divides the body into right and left parts.

spectrum, most of the brain may be herniated outside of the skull into a skin-covered sac.

Genetic profile

Most neural tube defects (80% to 90%) occur without a family history of the condition. They can have different causes and can result from both genetic and environmental factors. Neural tube defects are also found in disorders where people have an extra chromosome. Chromosomes are inherited from the parents and contain their DNA.

The risk of neural tube defects can be increased as the result of environmental exposures during pregnancy. For example, the risk of neural tube defects in the baby can be increased if during the pregnancy the mother:

- has insulin-dependent diabetes
- is obese
- uses certain antiseizure medications that interfere with folic acid metabolism
- uses opioids in the first two months of pregnancy
- has a high body temperature early in pregnancy
- drinks a lot of tea early in pregnancy
- has folic acid deficiency
- has vitamin D deficiency
- has vitamin B12 deficiency
- smokes cigarettes

Maternal folic acid deficiency may be the most common cause of neural tube defects. About 50% to 70% of neural tube defects can be prevented with maternal folic acid supplements during pregnancy. In some cases, the maternal folic acid deficiency may be due to a genetic defect in the pathway involved in the breaking down and converting of folic acid for use by the body (metabolism).

Neural tube defects. (Shutterstock/Vasilisa Tsouy)

Neural tube defects can have a genetic component. Some evidence that there is a genetic component is that the chance of having another child with neural tube defects is increased and that both identical twins are more likely to have a neural tube defect than are non-identical twins. After a couple has one infant with a neural tube defect, the recurrence risk is 3% to 5%. After the birth of two NTD-affected infants, the risk increases to 8% to 10%. This recurrence risk is lower than the 25% to 50% recurrence risk that is typically seen in disorders caused by variations in one major gene, which suggests that while there are genetic factors that predispose someone

to neural tube defects, in many cases an environmental trigger is also required.

Most of the variations in genes (mutations) that contribute to the development of neural tube defects are not known. Key genes that are being studied are those that influence the metabolism of folic acid and those that affect the organization of cells that form the spinal cord (planar cell polarity).

Pathogenic variants (mutations) in the *Vang2* gene, which is involved in development of the spinal column, can cause neural tube defects. In some rare cases, this

QUESTIONS TO ASK YOUR DOCTOR

- What symptoms can I expect if my child is born with an NTD?
- What treatments are available if my child is born with an NTD?
- What programs are available to assist in managing NTD?
- I am planning to become pregnant; what should I do to prevent NTD?

variant can be inherited, but in most cases, it happens when the embryo is developing. A baby can even develop a neural tube defect if only some of the cells have a variant in the *Vang2* gene. When some cells have a normal gene, and some have a variant, it is called mosaicism.

Demographics

Neural tube defects occur worldwide. It appears that the highest prevalence (about one in 100 pregnancies) occurs in certain northern provinces in China. An intermediate prevalence (about one in 300 to 500 pregnancies) has been found in Ireland and in Central and South America, and the lowest prevalence (fewer than one in 2,000 pregnancies) has been found in the Scandinavian countries. In the United States, the highest prevalence has occurred in the Southeast. Worldwide, there has been a steady downward trend in prevalence rates over the past 50 to 70 years, possibly due to better quality of life, nutrition, and access to medical care in most parts of the world.

Signs and symptoms

Because of the faulty development of the spinal cord and nerves, the nerves below the level of the defect fail to function and result in paralysis and loss of sensation below the spinal lesion. Since most defects occur in the lumbar region, the lower limbs are usually paralyzed and lack normal sensation. Furthermore, the bowel and bladder have inadequate nerve connections, causing inability to control organ function. Sexual function is likewise impaired. An abnormal buildup of spinal fluid (hydrocephaly) develops in most infants either before or after surgical repair of the spine defect.

In anencephaly, the brain is destroyed by exposure during intrauterine life. Most infants with anencephaly are stillborn or die within the initial days or weeks after birth.

Infants with encephaloceles have variable neurologic impairments, depending on the extent of brain involvement. When only the brain covering is involved, the individual may escape any adverse effects; however, when the brain is involved in the defect, impairments of the special senses, such as sight, hearing, and cognitive thinking, commonly result.

Diagnosis

At birth, the diagnosis is usually obvious, based on external findings. Prenatal diagnosis may be made with ultrasound examination after 12 to 14 weeks of pregnancy. Screening pregnancies can be carried out at 16 weeks by testing the mother's blood for the level of alpha-fetoprotein, which is made by the fetus. Open neural tube defects leak this fetal chemical into the surrounding amniotic fluid, a small portion of which is absorbed into the mother's blood and can be measured.

Treatment and management

No treatment is available for anencephaly. Aggressive surgical and medical management has improved survival and function of infants with spina bifida. Surgery closes the defect, providing protection of the spinal cord against injury and infection. One common complication that may occur before or after surgical correction is the accumulation of excessive cerebrospinal fluid (hydrocephaly) in the major cavities (ventricles) within the brain. Hydrocephaly is usually treated with the placement of a mechanical shunt, which allows the cerebral spinal fluid from the ventricles to drain into the circulation or another body cavity. A number of medical and surgical procedures have been used to protect the urinary system as well. Walking may be achieved with orthopedic devices. Encephaloceles are usually repaired by surgery soon after birth. The success of surgery often depends on the amount of brain tissue involved in the encephalocele. In some cases, surgical repair can be done before the baby is born.

It has been found that taking 400 micrograms of folic acid two to three months prior to conception, and two to three months following conception, protects against neural tube defects. While there are a number of foods (green leafy vegetables, legumes, liver, and orange juice) that are good sources of natural folic acid, synthetic folic acid supplementation is recommended, since it can be difficult to get enough folic acid from natural sources.

Prognosis

Infants with anencephaly are usually stillborn or die within the initial days of life. Eighty to ninety percent of infants with spina bifida can survive with surgery.

Paralysis below the level of the defect, including an inability to control bowel and bladder function, and hydrocephaly are complications experienced by most survivors. Intellectual function is normal in most cases.

The prognosis for infants with encephaloceles varies considerably. Small encephaloceles may cause no disability whether surgical correction is performed or not. Infants with larger encephaloceles may have residual impairment of vision, hearing, nerve function, and intellectual capacity.

Neurofibromatosis

Definition

Neurofibromatosis (NF) are a group of three genetic disorders that cause tumors of the nervous system. These disorders cause tumors of the supporting cells of the nerve and myelin sheath (neurofibromas). The disorders occur as neurofibromatosis type 1 ([NF1] or von Recklinghausen disease), neurofibromatosis type 2 (NF2), and Schwannomatosis (NF3).

Neurofibromatosis is a genetic disorder that causes tumors to grow on nerves. (Pornsak Paewlumfaek/Shutterstock)

Description

Neural crest cells are primitive cells that exist during fetal development. These cells eventually turn into cells that form nerves throughout the brain, spinal cord, and body. Collectively, this system of nerve cells is called the nervous system, which coordinates movement and sensation. Some nerve cells carry impulses from the brain to muscles or other peripheral structures, hence the name peripheral nervous system. Another group of nerve cells called the central nervous system are capable of transmitting sensation back to the brain for interpretation (such as feeling cold or hot).

In neurofibromatosis, a genetic defect causes these neural crest cells to develop abnormally. This results in numerous tumors and malformations of the nerves, bones, and skin.

Genetic profile

Both forms of neurofibromatosis are caused by a defective gene. NF1 is due to mutations in the *NF1* gene (17q11.2) and rarely by 17q11 microdeletion (only 5%). This gene provides instructions for making a protein called neurofibromin, produced in many types of cells, including nerve cells and cells that surround nerves, forming myelin sheaths, the fatty layers that protect certain nerve cells. As of 2015, over 1,000 NF1 mutations had been identified.

NF2 results from mutations in the *NF2* gene on chromosome 22q. The *NF2* gene provides instructions for making a protein called merlin (or schwannomin). It is produced in the nervous system, particularly in Schwann cells, which surround and protect nerve cells in the brain and spinal cord. It is believed to act as a tumor suppressor, meaning that it

Reggie Bibbs, a man afflicted with neurofibromatosis, sits with his mother, Dorothy. The disorder is characterized by skin changes and bone deformities. (Marie D. De Jesus/Houston Chronicle/AP Images)

KEY TERMS

Chromosome—A microscopic thread-like structure found within each cell of the body and consisting of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Mutation—An inherited or de novo change in the DNA sequence of the genome.

Neurofibroma—A soft tumor usually located on a nerve.

Schwannoma—A tumor that grows from the cells that line the nerves of the body (Schwann cells).

Tumor—An abnormal growth of cells. Tumors may be benign (noncancerous) or malignant (cancerous).

prevents uncontrolled cell growth. A lack of merlin allows Schwann cells to multiply excessively and form the tumors associated with NF2.

Both of these disorders are inherited as a dominant trait. This means that anybody who receives just one defective gene will have the disease. However, a family pattern of NF is only evident for about half of all cases of NF. The other cases of NF occur due to a spontaneous mutation (a spontaneous and permanent change in the structure of a specific gene). Once a spontaneous mutation has been established in an individual, it is then possible to pass the mutation on to any offspring. The chance of a person with NF passing on the *NF* gene to his or her child is 50%. There are different pathologic alleles (variations of the mutant gene). The frequency of spontaneous (new) mutations is very high; causes for this are still unknown.

Demographics

According to the National Institute for Neurological Disorders and Stroke (NINDS), an estimated 100,000 Americans have a neurofibromatosis. NF1 occurs in about 1 of every 3,000 to 4,000 births. Between 30% and 50% of new cases arise from a spontaneous mutation that can then be passed down. It is one of the most common genetic disorders that is dominantly inherited, and it represents the most common form of NF cases.

The incidence of NF2, a rare disorder, affects approximately 1 in 25,000 people. About 50% of patients inherit the disorder.

Schwannomatosis is a very rare form of NF that is both genetically and clinically different from NF1 and NF2. Only 15% of all cases are inherited.

Signs and symptoms

NF1 has a number of possible signs and can be diagnosed if any two of the following are present:

- The presence of café-au-lait (French for “coffee with milk”) spots. These are patches of tan or light brown skin, usually about 5 to 15 mm in diameter. Nearly all patients with NF1 display these spots.
- Multiple freckles in the armpit or groin area.
- Most patients with NF1 have tiny tumors called Lisch nodules in the iris (colored area) of the eye. Neurofibromas occur under the skin and are often located along nerves or within the gastrointestinal tract. They are small and rubbery, and the skin overlying them may be somewhat purple in color.
- Skeletal deformities, such as a twisted spine (scoliosis), curved spine (humpback), or bowed legs.
- Tumors along the optic nerve (the nerve cells that transmit a visual stimulus to the back part of the brain [the occipital lobe] for interpretation) cause vision disturbance and occur in about 20% of patients.
- The presence of NF1 in a patient’s parent, child, or sibling.
- Hypertension, or elevated blood pressure.

There are very high rates of speech impairment, learning disabilities, and attention deficit disorder in children with NF1. Other complications include the development of a seizure disorder (an abnormal firing of nerve cells in muscles, causing severe contractions, sometimes involving the whole body) or abnormal accumulation of fluid within the brain (a condition called hydrocephalus). A number of cancers are more common in patients with NF1. These include a variety of types of malignant brain tumors, as well as leukemia, and cancerous tumors of certain muscles (rhabdomyosarcoma), the adrenal glands (pheochromocytoma), or the kidneys (Wilms’ tumor).

NF2 patients have tumors along the eighth cranial nerve (vestibular schwannomas). The eighth cranial nerve has two branches: the acoustic nerves involved in hearing and the vestibular nerves involved in maintaining balance. Interfering with the function of these nerves results in a loss of hearing, dizziness, poor balance, and uncoordinated walking. Cataracts frequently develop at an unusually early age. As in NF1, the chance of brain tumors, gliomas, ependymomas (two types of tumors of the spinal cord), and meningiomas (tumors that grow in the protective layers surrounding the brain [meninges]) developing is unusually high. Peripheral neuropathy or

QUESTIONS TO ASK YOUR DOCTOR

- How do you inherit neurofibromatosis?
- What is the treatment for neurofibromatosis?
- Will I pass this condition to my children?

numbness in the extremities can occur as the tumors press on vital nerves or brain areas.

Schwannomatosis is a very rare form of NF that is both genetically and clinically different from NF1 and NF2. Only 15% of all cases are inherited. A mutation of the *SMARCB1/INI1* gene is associated with the familial form of the diseases. Characteristically these patients develop multiple schwannomas (tumors of the Schwann cells that are involved in the development of the protective myelin sheath that surrounds nerve cells) everywhere in the body except along the vestibular nerve. The main symptom is pain that occurs as the tumors press on the nerves and surrounding tissues.

Diagnosis

Diagnosis is based on the broad spectrum of clinical signs previously described, which usually can be detected by careful physical examination, ophthalmologic evaluation (visualizing the structures in the eye), and audiogram (test to measure hearing ability). Diagnosis of NF1 requires that at least two of the listed signs are present. Diagnosis of NF2 requires the presence of either a mass on the acoustic nerve or another distinctive nervous system tumor. An important diagnostic clue for either NF1 or NF2 is the presence of the disorder in a patient’s parent, child, or sibling. A test to detect a protein (the end-products of a gene) relevant to NF1 mutagenesis has been created, but accuracy for this procedure has not been established.

Monitoring the progression of neurofibromatosis involves careful testing of vision and hearing. X-ray studies of the bones are frequently indicated to detect for the development of deformities. CT scans and MRI scans are performed to track the development/progression of tumors in the brain and along the nerves. Auditory evoked potentials (the electric response evoked in the cerebral cortex by stimulation of the acoustic nerve) may be helpful to determine acoustic nerve involvement, and EEG (electroencephalogram, a record of electrical impulses in the brain) may be required for patients with suspected seizures. Regular blood pressure monitoring is also advised.

Treatment and management

There are no available treatments for the disorders that underlie either type of neurofibromatosis. To some extent, the symptoms of NF1 and NF2 can be treated individually. Skin tumors can be surgically removed. Some brain tumors and tumors along the nerves can be surgically removed or treated with chemotherapy or radiation therapy. Twisting or curving of the spine and bowed legs may require surgical treatment or the wearing of a special brace.

There is no known way to prevent the approximately 50% of all NF cases that occur due to a spontaneous change in the genes (mutation). New cases of inherited NF can be prevented with careful genetic counseling. A person with NF can be taught that each of his or her offspring has a 50% chance of also having NF. Special tests can be performed on the fetus during pregnancy to determine if the fetus will be born with this disorder. Amniocentesis (in which a needle is passed through the mother's abdomen into the amniotic sac, which contains the amniotic fluid and cushions the developing fetus) or chorionic villus sampling (a procedure involving extraction of a tissue sample from the placenta, the structure that connects the fetal blood with the mother, necessary for nutrient and waste exchange) are two techniques that allow small amounts of fetal DNA to be removed for analysis. The tissue can then be examined for the presence of the parent's genetic defect. Some families choose to use this information to prepare for the arrival of a child with a serious medical condition. Other families may choose not to continue the pregnancy.

Prognosis

Prognosis varies depending on the tumor type that develops. As tumors grow, they begin to destroy surrounding nerves and structures. Ultimately, this destruction can result in blindness, deafness, increasingly poor balance, and increasing difficulty with the coordination necessary for walking. Deformities of the bones and spine can also interfere with walking and movement. When cancers develop, prognosis worsens according to the specific type of cancer.

Neuronal ceroid lipofuscinoses

Definition

Neuronal ceroid lipofuscinoses (NCLs) are a family of about eight disorders affecting the nervous system. Most commonly they develop in infancy or childhood. Symptoms of the disorder include mental impairment, seizures, and the loss of sight and motor skills. These disorders result from an overaccumulation of lipopigments in neuronal cells and other bodily tissues. All mutations that are associated with NCLs are linked to genes that are involved in neural synapsis metabolism and the recycling of vesicle proteins.

Description

NCL is characterized by an abnormal build-up of lipopigments—substances made up of fats and proteins—in membrane-bound compartments within cells. The compartments are organelles called lysosomes

Batten disease: pedigree analysis chart (Gale)

and function in the breakdown of waste products and complex molecules produced by the cell. In NCL diseases, this process is disrupted, and lipopigments can accumulate. The accumulation of lipopigments can contribute to vision failure and the loss of mental and neurological functions beginning in early childhood.

NCL is the general term for a family of progressive neurological disorders. There are approximately eight disorders in the NCL family, although all of these disorders are often collectively referred to as Batten disease.

Genetic profile

The first notable description of NCL was in 1826 in Norway by Dr. Christian Stengel, who observed siblings that showed characteristics of the disease. The British pediatrician Frederick Batten performed clinical studies on several families in the early 1900s; the juvenile form of NCL was named after him. Batten also played an important role in defining the juvenile form of NCL as a different disorder from that of Tay-Sachs disease. NCLs are autosomal recessive disorders, which means that they occur when a child receives one copy of the abnormal gene from each parent.

Individuals with only one abnormal gene are known as carriers; they do not develop the disease but can pass the gene on to their own children. When both parents carry one abnormal gene their children have a one in four chance of developing an NCL disease.

Initially, NCL disorders were differentiated by the age of onset. These classifications included:

- Infantile NCL (Santavuori-Haltia)
- Late infantile NCL
- Juvenile NCL (Batten disease, Spielmeier-Vogt disease)
- Adult NCL (Kuf's disease, Parry's disease)

Now that the genes involved in the diseases have been identified, the associated genes classify the types of NCL. Mutations in eight genes have been found to contribute to NCL symptoms and also now serve as names for specific forms of NCL:

- CLN1 encodes an enzyme called palmitoyl-protein thioesterase 1 (PPT1). It is insufficiently active in infantile NCL.
- CLN2 produces an enzyme called tripeptidyl peptidase 1 (TPP1) that is an acid protease that degrades

proteins. The enzyme is insufficiently active in late infantile NCL.

- CLN3 is the major cause of juvenile NCL. *CLN3*, or battenin, is found in the membranes of the cell, most predominantly in lysosomes, and in related structures called endosomes. The protein's function is currently unknown.
- CLN5 causes variant late infantile NCL (vLINCL) and produces a lysosomal protein whose function has not been identified.
- CLN6 also causes late infantile NCL and encodes a protein called CLN6 or linclin. The protein is found in the membranes of the endoplasmic reticulum. Its function has not been identified.
- MFSD8 is a variant of late infantile NCL, also referred to as *CLN7*; it encodes the MFSD8 protein that is a member of a protein family called the major facilitator superfamily. Proteins in this superfamily are involved with transportation across the cell membranes. The precise function of MFSD8 has not been identified.
- CLN8 causes progressive epilepsy with intellectual disability. The gene encodes the *CLN8* protein, which is found in the endoplasmic reticulum and whose function has not been identified.
- CTSD is involved with congenital NCL (also referred to as *CLN10*) and encodes cathepsin D, a lysosomal enzyme. A deficiency of cathepsin D causes the disorder.

While not initially considered part of the NCL classification, northern epilepsy syndrome is a subtype of NCL that is reported only in people from northern Finland and those of Finnish descent. It is characterized by seizures that begin in early childhood and progress through adolescence. Intellectual disability is associated with the syndrome, and while the seizures may decrease with age, mental faculty does not return. In 1999, northern epilepsy syndrome was reclassified as an NCL disease when the missense mutation associated with the syndrome was found to occur in the *CLN8* gene. This mutation alters the lipid content of the brain, which affects brain function and produces the symptoms of the disease. Northern epilepsy syndrome is considered to be one of the milder forms of NCL disorders.

Demographics

NCLs are relatively rare, occurring in 2 to 4 of every 100,000 births in the United States. NCLs appear to be more common in children living in Northern Europe and Newfoundland, Canada. Although the disorder affects both genders equally on a genetic level, female patients show signs up to a year later than male patients and tend to die earlier from Batten disease.

KEY TERMS

Lipofuscin—Pigment granules that are produced from lysosomal degradation. Lipofuscin normally accumulates over time and with age.

Lipopigments—Substances made up of fats and proteins that can accumulate in different tissues of the body. They have a yellowish color to them under UV light. Lipopigments can result from oxidation of fatty acids and may be symptomatic of damage or aging.

Lysosome—A membrane-enclosed compartment in cells that contains many hydrolytic enzymes where large molecules and cellular components are broken down.

Neuronal ceroid lipofuscinoses—A family of eight genetically distinct progressive neurological disorders that are all a result of overaccumulation of lipopigments.

Signs and symptoms

Early symptoms of NCLs usually develop in early childhood at two or four years of age and include vision difficulties and seizures. There may also be personality and behavioral changes, slow learning, clumsiness, or stumbling by the time the child is between the ages of five and eight. Over time, the child can develop mental impairment or regression, worsening seizures, and the complete loss of vision and motor skills. NCL diseases are terminal and eventually lead to death in those who suffer from them.

Childhood forms of NCLs may first be suspected during an eye exam that displays a loss of certain cells. Because such cell loss can occur in other eye diseases, this sign alone cannot diagnose the disorder. An eye specialist who suspects an NCL disease may refer the child to a neurologist, who can analyze the medical history and information from various laboratory tests.

Diagnosis

Diagnostic tests used for NCLs include blood or urine tests that can detect abnormalities, skin or tissue sampling can measure the build-up of lipopigments in cells, electroencephalograms that display electrical activity within the brain that suggests a person has had seizures, electrical studies of the eyes that can further detect various eye problems common in childhood NCL, and brain scans can visualize changes in the brain's appearance. When the specific gene that causes the form

QUESTIONS TO ASK YOUR DOCTOR

- What physiological changes are associated with my child's NCL disease?
- What treatments are available to slow the progress of this condition?
- What treatments are available to make my child more comfortable and better adapted to this medical condition?
- What is the prognosis for this disorder?

of NCL is known, DNA testing can confirm the diagnosis. DNA analysis can also be used to identify unaffected family members as carriers when NCL is suspected. This analysis can be useful to those who are carriers in providing assistance in their own family planning.

Treatment and management

There is no widely used treatment to prevent or reverse the symptoms of NCLs. Anticonvulsant drugs are often prescribed to reduce or control seizures. Other medicines may be prescribed to manage other symptoms associated with the disorder. Physical and occupational therapies may also help people retain function for a longer period of time. There have been reports of the slowing of the disease among children who were given vitamins C and E and diets low in vitamin A. However, the fatal outcome of the disease remained the same.

In 1987, there was a small, phase I clinical study done at Cornell University using gene therapy to treat late infantile neuronal ceroid lipofuscinosis caused by the loss of the *CNL2* gene. An adeno-assisted virus 2 (AAV2) vector was used to introduce a normal copy of the *CNL2* gene into patients and showed that progression was slowed after treatment.

In 2006, stem cells were injected into the brains of six children who had NCL disease who, after six treatments, recovered speech and mobility. The study was a phase I clinical trial and focused on showing the safety of the procedure of transplantation and the use of stem cells in the treatment of neurological disorders. These patients were followed for 12 months after the treatment and showed normal progression of the disease.

Since 2010, research groups at the University of Rochester and Cornell University have been actively pursuing use of gene therapies in the treatment of Batten disease and other forms of NCL.

Prognosis

People with NCL disease may become blind, confined to bed, and unable to communicate. NCLs are typically fatal by the late teens or 20s. Some people with late-onset disease, however, can live into their 30s.

Nevoid basal cell carcinoma

Definition

Nevoid basal cell carcinoma syndrome (NBCCS) is primarily a genetic skin cancer condition. The syndrome derives its name from the cancerous skin lesions that typically begin in the third decade of life. However, the name is not completely satisfactory as there are other manifestations of the syndrome.

Description

A condition that was first described in 1894, nevoid basal cell carcinoma syndrome has been found in mummies dating back to 1000 b.c. However, the condition was brought to the attention of the medical community by Dr. Robert Gorlin, and thus bears the alternative name Gorlin syndrome. Other names include Gorlin-Goltz syndrome and basal cell nevus syndrome.

While NBCCS often leads to cancer, it can also result in various other physical findings and birth defects. The most common cancer is that of the skin, known as basal cell carcinoma. However, medulloblastoma (brain cancer) and ovarian cancer are also possible. Also frequently present are cysts (fluid-filled sacs) of the skin and jaw, palmar and plantar pits (slight depressions on the surface of the skin), a non-cancerous growth on the heart known as a fibroma, macrocephaly, and various skeletal problems.

Genetic profile

NBCCS is caused by mutations in a gene known as “patched” (*PTCH*). *PTCH* is located on chromosome 9. It is believed to be a tumor suppressor gene. The normal role of such genes is to prevent the growth of tumors. They do this by controlling cell growth and division. It is the presence of uncontrolled cell growth that can lead to a tumor.

NBCCS is inherited in an autosomal dominant manner, meaning that only one of the two *PTCH* genes found in every cell of the body must be mutated in order to have NBCCS. If a person has a mutation in just one of their *PTCH* genes, the disease will be present. This will include some of the signs and symptoms of the condition.

In about 50% of cases, a mutation in the *PTCH* gene may be inherited from a parent with NBCCS. In the other 50% of cases, a mutation can also occur by chance, in an individual without a family history of NBCCS. If the mutated gene is inherited from a parent, the symptoms of the disorder may be very different than those present in the parent. Some individuals will be more severely affected than others, even if they are all from the same family.

Once an individual has a *PTCH* mutation, there is a 50% chance with each pregnancy that the mutated *PTCH* gene will be passed on. If inherited, that male or female will have NBCCS.

While an individual with NBCCS will have a mutation in one of their two *PTCH* genes, it is the development over time of a second *PTCH* mutation in skin cells that actually leads to the development of the basal cell carcinomas. This second mutation is believed to occur

by chance, with the exact factors leading to a second mutation not yet fully understood. A second mutation in other cells may also lead to the other types of growths that can occur in NBCCS, including cardiac and ovarian fibromas, as well as medulloblastoma.

Demographics

NBCCS occurs in an estimated 1 out of every 57,000 individuals worldwide. However, this may be an underestimation of the true prevalence. While NBCCS is seen in all ethnic groups, individuals of Caucasian descent tend to exhibit cases of skin cancer more frequently than individuals of African descent. Approximately 0.4% of all cases of basal cell carcinoma are caused by the NBCCS.

Signs and symptoms

The characteristics associated with NBCCS are variable. The most prevalent symptom of this condition is skin cancer. Small growths (1–10 mm [0.04–0.4 in.] in diameter) on the skin can occur during as early as two years of age. However, if not removed, these can develop into basal cell carcinomas by as early an age as puberty. The number of growths may vary from just a few to thousands.

Medulloblastoma, a type of brain cancer, occurs in 3%–5% of individuals with NBCCS. It typically presents around two years of life and occurs in males more commonly than females. Seizures have occasionally been seen as part of this condition but are not felt to be related to the presence of medulloblastoma.

An increased risk for other cancers has been proposed to be associated with this syndrome. However, as of the year 2015 this has not been proven.

Jaw cysts are another common sign of NBCCS. They typically first appear around 15 years of age. Although often large, they rarely cause symptoms other than tooth displacement. The number of cysts can vary greatly and they do have a tendency to recur after surgical removal.

Various birth defects are more common in NBCCS. These can include polydactyly, cleft lip, cleft palate, various eye abnormalities, minor kidney anomalies, rib problems, and spinal anomalies (such as unusually shaped bones of the spinal column). Interestingly, overall height in individuals with NBCCS is slightly higher than average.

There are many possible eye abnormalities, such as cataracts found at birth, unusually small eyeballs, cysts in the eye, failure of the eye to develop fully, shaky or jerky eye movements, and problems with the nerve connecting the eye to the brain.

Rib anomalies are found in 45%–60% of individuals with NBCCS. They generally do not cause any problems,

although can be a clue to the diagnosis. Different rib problems associated with NBCCS can include partially missing ribs, ribs that split into two (known as bifid ribs), and ribs that fuse together.

The kidney problems are not as common a symptom, occurring in 14% or less of individuals with NBCCS. The most serious condition is when both kidneys are fused together, known as a horseshoe kidney. Unusually shaped kidneys, cysts, a single missing kidney, and duplication of parts of the kidney can also occur. However, as many of these kidney problems do not tend to cause health issues, they are not always detected unless specifically looked for.

A small percentage of males will have undescended testicles, the loss of the ability to smell, unusual breast tissue development, and sparse facial and body hair. These can all be signs of hormonal or endocrine disturbance.

Other features often include macrocephaly and growths (fibromas) in the heart and ovaries. Finally, pits or lesions in the palms of the hands or soles of the feet are very common, harmless findings.

Diagnosis

To make a diagnosis of NBCCS an individual must have at least two major and one minor characteristics that meet the diagnostic criteria. Alternatively, one major and three minor criteria can be present. Since there are many different symptoms that are considered major and minor, no two individuals with NBCCS will be exactly alike in their manifestations.

Examples of major criteria include:

- More than five basal cell carcinomas, or one before the age of 30 years
- Jaw cysts
- Two or more palmar or plantar pits
- Deposits of calcium or other salts on parts of the brain that can be seen on x-rays
- A first-degree relative (sibling, parent, or child) known to have NBCCS

Examples of minor criteria include:

- Macrocephaly
- A cleft lip or palate
- Eye abnormalities of various types
- Polydactyly
- Ovarian or cardiac fibromas
- Childhood medulloblastoma
- Rib or spinal anomalies of various types

There is no exact age by which someone can be assured they do not have NBCCS. This is because each possible

KEY TERMS

Autosomal dominant—A pattern of inheritance in which only one nonworking gene is needed to display the trait or disease.

Basal cell carcinoma—A cancer originating from the skin.

Carcinoma—Cancer that forms from tissue that covers various surfaces, glands, and organs of the body, such as the skin.

Cleft lip—An opening in the upper lip that can extend to the base of one or both nostrils.

Cleft palate—A congenital malformation in which there is an abnormal opening in the roof of the mouth, creating a connection between the nasal passages and the mouth.

Fibroma—An unusual growth of the tissue that provides stability and support in the body.

Genes—The units of inheritance, which contain the instructions to make one or more proteins; genes are located on chromosomes.

Macrocephaly—An unusually large head.

Medulloblastoma—A type of brain cancer.

Mutation—A change in a gene that causes it to either not function, or malfunction. This will result in manifestation of a disease, or alter a trait.

Palmar—Referring to the palms of the hand.

Plantar—Referring to the sole of the foot.

Polydactyly—The presence of extra fingers or toes.

Prevalence—The number of cases of a disease in a population at a specific period of time.

symptom can develop at a different time. For example, 90% of affected individuals develop jaw cysts by their second decade, but 10% of affected individuals never develop a single basal cell carcinoma. However, enough symptoms are usually present by the time the patient reaches their 20s or 30s that a diagnosis may be possible.

Alternatively, using a blood sample to test the *PTCH* gene for the presence of a mutation can also make a diagnosis of NBCCS. However, only 65%–80% of individuals with NBCCS will actually have a detectable mutation using the technology available as of 2015.

Treatment and management

Removal of the multiple skin tumors and jaw cysts is recommended. Failure to do so can lead to both the

development of basal cell carcinomas, along with social difficulties due to the disfiguring nature of these tumors. Removal of jaw cysts should be undertaken by an oral surgeon and the basal cell carcinomas by a plastic surgeon. Radiation therapy should be avoided as these can cause further development of the basal cell carcinomas.

Ovarian fibromas, if present, can be surgically removed. The same is true for cardiac fibromas, although they do not usually cause symptoms.

Since manifestations of NBCCS can vary, any affected individual should be monitored carefully by the appropriate specialist. These include a dermatologist (skin doctor), dentist or orthodontist, ophthalmologist (eye doctor), pediatrician, and geneticist (specialist in genetics). Special precautions should be taken to avoid radiation, in the form of both radiation treatment and sun exposure, as this increases the risk to form basal cell carcinomas. Typical methods to reduce sun exposure, such as sun block and hats, should be used.

Phototherapies (treatment of disease by means of light rays) and topical treatments (skin creams based on vitamin A) are currently under investigation as possible means of treatment.

Prognosis

The life expectancy of individuals with NBCCS is considered to be essentially average. However, the key to this is diagnosis and proper treatment.

Developmental delay can be associated with the enlarged head size, but intelligence is often normal. Therefore, head circumference should be monitored throughout childhood and any rapid changes evaluated by magnetic resonance imaging (MRI) right away.

Next-generation sequencing

Definition

Next-generation sequencing (NGS) encompasses various technologies for rapidly determining DNA sequences. It is also called massively parallel sequencing or deep resequencing. NGS simultaneously sequences large numbers of relatively small DNA fragments. The sequences are then arranged in the correct order (aligned), using computers and bioinformatic techniques, to reveal the sequences of genes, whole exomes (the portion of DNA that codes for proteins), or whole genomes (all of the DNA in a cell, tissue, or organism). NGS has greatly increased the speed and reduced the cost of DNA sequencing, leading to many new genetic applications.

Description

DNA sequencing determines the exact order of nucleotide bases—the building blocks of DNA (designated A, T, G, and C)—to reveal an individual's genetic code. Whole-genome sequencing (WGS) determines the entire sequence of the more than three billion nucleotides in human cells. Whole-exome sequencing (WES) determines only the 1%–3% of DNA that encodes the instructions for making proteins. Targeted sequencing determines the DNA sequence of specific genes or regions of a chromosome.

NGS has revolutionized the use of DNA sequencing for identifying genetic disorders and variations in DNA sequences that increase susceptibility to specific diseases. It can readily determine relationships between individuals and reveal their ancestry. It is used to determine the DNA sequences of other organisms, including the trillions of bacteria and other microorganisms that live in and on the human body—the microbiome. NGS of ancient DNA has revolutionized the study of human history and evolution.

Origins

The original method for sequencing DNA—Sanger sequencing or first-generation sequencing, developed by

Frederick Sanger in 1975—enabled large-scale DNA sequencing for the first time. Sanger sequencing has since been automated and is still used to sequence short pieces of DNA, but, although it is extremely accurate, it is time-consuming, labor-intensive, and expensive. Sanger sequencing separates the DNA “double helix” into its two complementary strands and cuts it in such a way that the DNA fragments terminate at every possible nucleotide. Then the terminal nucleotide bases are labeled with a fluorescent compound. The DNA fragments are separated and ordered by size using a technique called electrophoresis. The fluorescent-labeled terminal base of each fragment (A, T, G, or C) is then identified to “read” the DNA sequence.

When the Human Genome Project (HGP) set out to determine the entire DNA sequence of humans in 1990, it required thousands of scientists at 20 large centers around the world performing Sanger sequencing on various regions of the genome. This spurred the development of new technologies that sequenced small DNA fragments and compiled these sequences into the correct order using powerful new computer software. These new technologies led to the completion of the HGP in 2003, several years ahead of schedule, and spearheaded the development of NGS. NGS first became available in 2005 and has developed and improved steadily since then. With NGS, an individual’s entire genome can be sequenced in just a few days. This has revolutionized genetic science and ushered in the beginnings of “personalized medicine” that can diagnose and treat disease according to an individual’s unique DNA.

NGS sequences thousands or millions of DNA fragments simultaneously (massively parallel), but the fragments are usually much shorter than those used for Sanger sequencing. This results in an immense amount of data. Thus, NGS requires huge data storage and analysis capabilities, which has ushered in the new science of bioinformatics to align (collate) the sequences and apply statistical and computational analysis to the genomic data. With NGS, the sequencing is so fast that the data processing and analysis have become the time-limiting factors.

Procedures

The advent of NGS has engendered fierce competition among biotechnology companies to develop commercial platforms for different types of sequencing using a variety of technologies. Each method has advantages and disadvantages. Genomic DNA is obtained from blood, saliva, or tissue. In a typical procedure, the two strands of the DNA double helix are separated and cleaved into fragments. The fragments can be amplified to make many copies using a procedure called

KEY TERMS

Bioinformatics—The use of computer science for collecting, classifying, and analyzing genetic information.

Epigenetic—A modification outside of the actual mutation of the DNA sequence, such as the addition of a methyl group.

Exome—The protein-encoding DNA sequences (exons) of the genome.

Genome—The entire DNA sequence of a cell or organism.

Human Genome Project—An international effort begun in 1990 and completed in 2003 to locate and identify the 100,000 genes on the 46 human chromosomes.

Microbiome—All of the microorganisms normally present in a given environment, such as the human body.

Nucleotide—A small molecule composed of three parts: a nitrogen base (a purine or pyrimidine), a sugar (ribose or deoxyribose), and phosphate; they serve as the building blocks of nucleic acids (DNA and RNA).

Personalized medicine—Diagnosis and treatment based on the DNA sequence of an individual or a cancer.

Polymerase chain reaction (PCR)—A laboratory process used to make a large number of copies of specific genetic information from small amounts of DNA.

RNA-sequencing—Next-generation sequencing (NGS) of RNAs in a cell or tissue.

Single-nucleotide polymorphism (SNP)—Single-nucleotide variant (SNV); a variation or point mutation in a single-nucleotide building block of DNA.

Whole-exome sequencing (WES)—Sequencing of all the protein-encoding DNA (exons) in a genome.

Whole-genome sequencing (WGS)—Sequencing of all the DNA in a genome.

polymerase chain reaction (PCR). The complementary strands of the fragments are rebuilt using nucleotide bases with fluorescent tags. A special laser camera records the incorporation of the complementary fluorescent-labeled bases into the growing DNA chains. A complete genomic sequence can be run in about three days, with an error rate of 1 base per 1,000.

Although the 1000 Genomes Project and similar endeavors are using NGS to sequence and compare whole human genomes, in general, WGS is still too expensive for large-scale sequencing to compare populations. WES is less expensive than WGS and more comprehensive than genome-wide association studies (GWAS), which use markers called single-nucleotide polymorphisms (SNPs) to identify common genetic variants that are risk factors for disease. WES covers only 2%–3% of the genome but includes the sequences that are most likely to be relevant. An individual's genome usually contains 3–4 million nucleotide changes or SNPs that differ from reference human genomes, but most of these are not significant changes. About 85% of disease-causing inherited mutations occur within exons—the protein-encoding portions of DNA—and these can be detected by WES. Thus, WES is a cost-effective means for analyzing genetic disorders that run in families, as well as for association studies in populations.

As of 2015, WES and NGS systems were variants on the same procedure. Genomic DNA is cut into fragments of about 500 bases to create what is called a “shotgun library.” Adapters are attached to the ends of the DNA fragments to serve as “primers” for PCR amplification. The amplified DNA library is hybridized to short complementary DNA sequences called oligonucleotides in the same way that the two complementary strands of the double helix hybridize by base pairing. The oligonucleotides are specific for exons and are called “baits.” Molecules of biotin are attached to the oligonucleotides, and the biotin binds to the protein streptavidin that is attached to magnetic beads. Thus, the DNA-bait hybrids bind to the beads and represent the exons in the genome (an exon-enriched library). The separated exons are again amplified by PCR on slides or plates to produce enough DNA for sequencing. Fluorescent nucleotides, DNA polymerase (the enzyme that adds nucleotides to the growing DNA chain), and short pieces of DNA called sequencing primers are added to the fragments, which are generally 25–350 nucleotides in length. As the fluorescently tagged bases are incorporated into each strand, laser activation records the fluorescence. Computers can determine many sequences simultaneously, and each fragment is sequenced 20–30 times.

Another type of NGS exome sequencer uses pH. Each time complementary bases from two DNA strands join together (hybridize), they release hydrogen ions, which cause miniscule increases in acidity that can be measured. As of 2015, this method could sequence an entire exome in less than one day for about \$400. Sequencing specific genes is even faster and cheaper.

WES reveals 20,000–25,000 SNPs, compared to the several million SNPs in a whole-genome sequence. Data

QUESTIONS TO ASK YOUR DOCTOR

- Can next-generation sequencing (NGS) be used to diagnose my disorder?
- Will whole-genome sequencing or whole-exome sequencing be performed?
- Can next-generation targeted sequencing be used?
- How much does NGS cost?
- Will my insurance pay for NGS?

processing compares these SNPs with control data to enrich for those that may be relevant. This filters out all but 500–700 SNPs. These remaining SNPs are examined more carefully, for example, to see whether they are in genes of particular interest or are changes that do not fit the inheritance pattern of the disorder being studied. Software can also predict mutations that may have significant effects on protein products. An important advantage of WES is that it may detect very rare mutations that cause genetic disorders or mutations in a gene that was not expected to be involved in a disorder.

Targeted sequencing can detect variants in genes of interest much faster and cheaper than WGS or WES. Targeted NGS methods include PCR-based target enrichment for clinical diagnostic testing of specific genes and hybridization-based enrichment methods that can cover larger genomic regions.

Limitations

The volume of data produced by NGS can be very extensive. A single run may produce millions or billions of short reads of about 50–150 nucleotides. This data must be quality controlled, stored, assembled, aligned, and annotated.

- Base calling is the process of identifying the nucleotide bases from the fluorescent signals produced by the sequencer. Different NGS platforms tend to produce different types of sequencing errors, and base callers must estimate the error frequencies.
- Incorrect alignment of sequences is a common problem. Often, sequences will be mapped to multiple locations on a reference genome. Several different strategies have been developed to deal with these “multi-reads.”
- Reconstructing a genome without a reference sequence requires longer sequenced fragments, and repeated

sequences can make such *de novo* assemblies very difficult.

- Hundreds of gigabytes of raw sequence data must be stored for potential future analysis and interpretation as analytic algorithms improve and genetic knowledge increases. Even shipping the data from the sequencing facility to the data analysis center can be a challenge.

There are other common problems with NGS:

- NGS requires several milligrams of DNA. This can be obtained easily from a few milliliters of blood, but obtaining enough DNA from tissue can be difficult.
- Coverage or depth is the average number of times that each nucleotide in a sequence is identified. Low-coverage sequencing identifies a given nucleotide only once or twice in only one or two reads. Thus, low coverage can easily result in misreading errors that may misidentify or miss a mutation.
- If the sequence is slightly misaligned with the reference genome, small base substitutions, insertions, and deletions can be missed. Alignment problems can also mistakenly indicate a mutation.
- Both WGS and WES identify thousands or millions of variations (SNPs), and it can be very difficult to determine which of these are relevant.
- Some control or reference genomic databases may contain unrecognized pathogenic mutations. In such cases, an important mutation may be discarded early in the analysis.

Cancerous tumors have unique genomes with many mutations, and sequencing of these genomes is an important application of NGS. However, routine methods for storing tumor tissues can lead to DNA degradation and chemical modification of nucleotides that cause sequence alterations. Variability of the genomes within the same tumor tissue or among different tumors from the same individual is also a challenge that must be overcome for personalized cancer diagnosis and treatment.

WES has some specific limitations:

- WES covers most—but not all—of the exome.
- WES misses DNA variations or mutations that are outside of the exome but that may affect the activity of a gene and the resulting protein production. These types of variations or mutations require more extensive sequencing or even WGS.
- WES sequences many short DNA fragments. Because short fragments are often repeated throughout the genome, they can be difficult to align properly. About 15%–30% of short fragments cannot be definitively assigned to a single location in the genome.
- Some disorders, such as Huntington disease, are caused by specific sequences of DNA that are repeated an

abnormal number of times. These are called “repeat expansions” and are not generally recognized by WES.

Applications

As of 2015, an individual’s entire genome could be sequenced for \$1,000 or less—cheaper than many routine medical tests. Thousands of human genomes are being sequenced to identify common and rare variations and disease-causing mutations. Projects such as the 1000 Genomes Project will identify variants that are present in only 1% of a population. NGS is also identifying many very rare and poorly understood genetic disorders. Finally, NGS is being used to sequence thousands of plant and animal genomes, as well as the genomes of billions of microorganisms that make up the human microbiome and many millions more that are present in the environment and have never been identified. NGS also can be used to identify epigenetic markers—chemical modifications to DNA that affect the activity of genes without changing the DNA sequence.

Cancer diagnosis and treatment stand to benefit from NGS, perhaps more than any other field of medicine. Cancers are characterized by mutations that differ from the individual’s normal genome. Furthermore, cancers that have spread (metastasized) can contain genomes that differ from the original cancer. Since many cancer treatments depend on the presence of specific mutations, the ability to rapidly sequence cancer genomes and compare them with the individual’s normal genome is expected to greatly improve cancer treatment and prognosis as the technology becomes more available and the costs continue to fall.

In addition to sequencing DNA (deoxyribonucleic acid), NGS can be used to sequence RNA (ribonucleic acid). RNA is a single strand that is complementary to a DNA strand, with “U” in place of “T,” and is copied (transcribed) from a DNA strand. There are many different types of RNA in cells, including messenger RNA (mRNAs) that produces proteins from protein-encoding genes. RNA-sequencing (RNA-seq) is “transcriptome” sequencing by NGS—the sequencing of all of the RNA present in cells, tissues, or organisms. Among other function, RNA-seq can identify and quantify which genes are active in specific cells or tissues at a given time. RNA-seq can also identify and quantify RNA that does not code for proteins but that have regulatory roles in the cell. RNA-seq has proved particularly useful for identifying gene fusions and aberrant nonprotein-coding RNA that are important in various cancers.

Third-generation sequencing

New sequencing platforms—called third generation—are being developed. These technologies sequence DNA directly, avoiding much of the sample preparation

required for Sanger and NGS sequencing. One emerging technology—single-molecule sequencing—directly sequences individual DNA or RNA molecules in biological samples without amplification.

Margaret Alic, PhD

NGLY1 deficiency

Definition

The *NGLY1* gene supplies the instructions for producing an enzyme called N-glycanase 1. This enzyme removes sugar molecules from damaged proteins to target the proteins for destruction by the cell. N-glycanase 1 enzyme is for the recycling of cellular waste products. Mutations (changes) in the *NGLY1* gene can cause an

inherited genetic disorder known as congenital disorder of deglycosylation (CDDG) or *NGLY1* deficiency. CDDG has a variety of signs and symptoms, including developmental delays, an inability to produce tears, and liver disease.

Since this disorder has only recently been identified—with only one or two descriptions of symptoms and possible treatments—the information below is an example of how many new genetic syndromes are now being treated and redefined as specific genetic disorders.

Description

N-glycanase 1, encoded by the *NGLY1* gene, is the enzyme that is responsible for removing sugar chains called glycans from misfolded (nonfunctional) N-linked glycoproteins. N-linked glycoproteins are proteins that have sugars attached to a nitrogen (N) atom on asparagine amino acid residues in the protein. N-glycanase 1 is present in the cytoplasm of most cells. It is part of an important cellular pathway known as the endoplasmic reticulum-associated degradation (ERAD) pathway, which is responsible for identifying and breaking down misfolded glycoproteins. Once N-glycanase 1 removes the glycan chain, the protein can be degraded by a protein complex known as the proteasome. In the absence of functional N-glycanase 1, cells can become clogged with misfolded and damaged proteins. Because N-glycanase 1 is important for cells throughout the body, a deficiency of the enzyme can have wide-ranging effects. N-glycanase 1 deficiency, or CDDG, is a member of a family of rare genetic disorders called congenital disorders of glycosylation (CDG), in which sugars are not properly attached to proteins. At least some cases of CDG had been associated with the *NGLY1* gene before the identification of CDDG.

In 2012, *NGLY1* deficiency became the first congenital (present at birth) deglycosylation disorder to be described. The story of its discovery has been recounted in articles by Matthew Might, the father of an affected child (Bertrand), and others. It is illustrative of the ways in which new genetic techniques and new media are combining forces to identify rare genetic disorders and connect affected families, with the goals of developing treatments and possibly cures.

Bertrand Might appeared normal at birth except for severe jaundice (yellowing of the skin and eyes indicating liver dysfunction), which is not unusual in newborns. He developed normally for the first two months of life, and then his development began to slow. By six months of age, he had lost almost all motor control. Might had no detectable brain damage, and his blood tests were normal except for extremely high levels of alpha-fetoprotein

KEY TERMS

Alpha-fetoprotein (AFP)—A fetal blood protein found in amniotic fluid.

Autosomal recessive—A pattern of genetic inheritance in which two abnormal genes are required to express a trait or disorder.

Congenital disorder of deglycosylation (CDDG)—*NGLY1* deficiency or N-glycanase 1 deficiency, in which sugar chains cannot be removed from misfolded proteins so that they can undergo degradation; caused by mutations in the *NGLY1* gene.

Congenital disorder of glycosylation (CDG)—A family of genetic disorders that includes *NGLY1* deficiency (congenital disorder of deglycosylation), as well as disorders in which sugars are not properly attached to proteins (glycosylation).

Endoplasmic reticulum—An interconnected system of membranes that is involved in protein synthesis and the transport of materials within cells.

Endoplasmic reticulum-associated degradation (ERAD)—An important cellular pathway that includes N-glycanase 1 and is responsible for breaking down (degrading) misfolded glycoproteins.

Glycoproteins—Proteins with added sugar molecules.

N-glycanase 1—An enzyme encoded by the *NGLY1* gene that removes (cleaves) sugars called glycans from misfolded proteins.

Whole-exome sequencing (WES)—Sequencing of the 1%–3% of the DNA in the genome that encodes for proteins; used to identify genetic disorders.

(AFP). Ataxia telangiectasia (A-T), a degenerative, fatal, autosomal recessive genetic disorder, was the only known syndrome characterized by both high AFP and movement disorders. However, his symptoms differed from A-T, and a genetic test for A-T came back negative. He continued to have signs of liver dysfunction and, at eight months of age, his development halted. The discovery of chains of sugar molecules in Might's urine pointed to a family of rare genetic disorders known as inborn errors of cellular metabolism. These included CDG, in which the absence of an enzyme prevents sugars from being properly attached to proteins. Although the clinicians at Duke University were unable to diagnose the specific disorder, they discovered that his abnormal movements were actually different forms of epileptic seizures. In addition, Might's parents suddenly realized that

in his two years of life, although he cried, he had never produced tears. Eventually, the child was also diagnosed with a heart defect known as long QT syndrome.

The Duke physicians became convinced that Might suffered from a previously undescribed genetic syndrome, and they decided to sequence the DNA of the entire exomes of the child and his parents to see if they could find a mutation. The exome consists of the 2%–3% of human DNA that carries the instructions for making proteins. About 85% of disease-causing mutations are located in the exome. Whole-exome sequencing (WES) revealed that Might's parents each carried a different mutation in one of their two *NGLY1* genes, and he had inherited both of these mutated genes, leaving him with no functional N-glycanase 1. At first, it was believed that Might was the only human with CDDG or N-glycanase 1 deficiency. However, through his parents' efforts, especially Matthew Might's blog, at least 15 more children with CDDG were soon identified. The Might family's well-publicized story established WES as a new paradigm for identifying previously unrecognized genetic disorders.

Genetic profile

The *NGLY1* gene is located on the short arm (p) of chromosome 3 at 3p24.2. Mutations in *NGLY1* are inherited in an autosomal recessive pattern, meaning that an individual must inherit two mutated genes, one from each parent, in order to develop the disorder. Parents may be carriers of one mutated *NGLY1* gene and have no symptoms of the disorder. However, each of their children has a 25% risk of inheriting both mutant genes and a 50% risk of inheriting one mutated gene and being a carrier of the disorder.

As of 2015, the majority of known patients with *NGLY1* deficiency had a specific nonsense mutation—a mutation that does not code for an amino acid in the protein, so that the protein ends with the amino acid that preceded the mutation. This particular mutation appears to cause severe disease, although it is expected that more *NGLY1* mutations will be identified that cause a wider range of symptoms. From his father, Bertrand Might inherited the *NGLY1* nonsense mutation called R401X, meaning that instead of the amino acid arginine at amino acid position 401 in the protein, the N-glycanase 1 protein ends prematurely at this position. From his mother, he inherited an *NGLY1* gene that contained a frameshift mutation that changed the DNA sequence of the gene and the resulting amino acid sequence of the protein. As a result, Might had barely detectable levels of N-glycanase 1. Because his parents each had one normal *NGLY1* gene and one mutated *NGLY1* gene, they had lower-than-normal levels of N-glycanase 1. Five other

QUESTIONS TO ASK YOUR DOCTOR

- Why do you think my child might have *NGLY1* deficiency?
- Is genetic testing available for *NGLY1* deficiency?
- Should other family members be tested for *NGLY1* gene mutations?
- What are the chances that we could have another child with this disorder?
- What treatments are available for my child?

patients with CDDG from three families, who were all of European descent, were identified as having the same R401X nonsense mutation in both of their *NGLY1* genes (homozygous mutations). Several other *NGLY1* mutations that cause CDDG have also been identified.

Demographics

CDDG is presumed to be extremely rare, since Might was the first identified case worldwide. Nevertheless, within a few months of his diagnosis, several more cases had been identified. Many of the children subsequently diagnosed with *NGLY1* deficiency had previously been diagnosed with Rett syndrome or a mitochondrial disorder, because the signs and symptoms are similar. CDG is also extremely rare, with fewer than 500 known cases in the United States.

Signs and symptoms

The signs and symptoms of *NGLY1* deficiency vary greatly and can be markedly different between males and females. Signs and symptoms include the following:

- global developmental delay
- movement disorders, including involuntary movements
- reduced or absent tear production (hypolacrima or alacrima, respectively), leading to ulceration and scarring of the cornea
- liver dysfunction, including elevated liver enzymes that may tend toward normal values over time
- a relatively small head (microcephaly) that may be present at birth or become apparent over time
- diminished reflexes or complete absence of reflex responses
- seizures in about half of patients, usually intractable and including sudden jerks (myoclonic seizures); drops, such as sudden dropping of the head (atonic seizures); and spells of staring (absence seizures)

- hypotonia (poor muscle tone)
- peripheral neuropathy—pain, numbness, muscle weakness, and atrophy of the peripheral nerves
- small hands and feet
- strabismus—eyes that wander in different directions

Diagnosis

Various clinical tests may suggest *NGLY1* deficiency, including the following:

- liver biopsy showing inflammation and substances stored in liver cells (vacuolization) that are presumed to be accumulated misfolded glycoproteins
- elevated liver transaminase levels
- sometimes elevated AFP levels
- abnormal oligosaccharides (sugars) in the urine, including keratan sulfate, heparan sulfate, and chondroitin sulfate
- abnormal brain features on magnetic resonance imaging (MRI), including enlarged ventricles (the chambers in the brain containing cerebrospinal fluid), delayed myelination (the covering of nerve fibers with white sheaths), loss of myelin covering nerve cells, and sometimes loss of nerve cell axons
- abnormal electroencephalography (EEG)
- normal results on tests for CDG

As of 2015, genetic testing for *NGLY1* mutations was available through the Emory Genetics Laboratory and the Baylor College of Medicine.

Treatment and management

As of 2015, treatment of *NGLY1* deficiency was directed at managing symptoms. For example, Might's seizures were treated with an antiseizure medication, which was only partially effective. He then went on a ketogenic diet, which is a very high-fat diet that forces the body to switch from glucose to ketones as an energy source. For reasons that are not well understood, a ketogenic diet is often effective for intractable epilepsy. Might's seizures diminished on the diet, but he developed tonic (stiffened muscle) seizures. Subsequently, he was injected twice daily with high doses of adrenocorticotrophic hormone (ACTH), which can sometimes halt intractable epileptic seizures. Although ACTH was effective in halting the seizures, the side effects were severe, and he developed a serious respiratory infection from the suppression of his immune system. After it was discovered that Might had severe vitamin deficiencies because his liver was unable to store vitamins, large doses of vitamins enabled him to form some tears for the first time. It has been suggested that certain antioxidants may

be useful for reducing stress on endoplasmic reticula in cells that are clogged with undegraded abnormal proteins.

Prognosis

The long-term prognosis for children with *NGLY1* deficiency is unknown. Symptoms may improve for a time but usually return. In the future, it may be possible to treat CDDG with synthetic N-glycanase 1.

Margaret Alic, PhD

Light micrograph of bone marrow from a patient with Niemann-Pick disease, an inherited metabolic disorder in which a fatty substance called sphingomyelin accumulates in the spleen, lungs, liver, and bone marrow, sometimes the brain as well. (CNRI/Science Source)

main types of Niemann-Pick disease: NP type A (NPA), NP type B (NPB), and NP types C1 (NPC1) and C2 (NPC2). These types are based on the genetic mutations involved and the symptoms.

Description

Niemann-Pick disease is inherited through an autosomal recessive trait. The different types of NP are characterized by an abnormal accumulation of sphingomyelin. A sphingomyelin is any group of sphingolipids (consists of a lipid and a sphingosine) containing phosphorus. Accumulation occurs primarily in the tissue of the nervous system, including the brain.

Some characteristics of Niemann-Pick disease may be common for all types. Common symptoms include jaundice, hepatosplenomegaly (enlargement of the liver and spleen), physical and mental impairment, and feeding difficulties. Symptoms for most types of Niemann-Pick disease are seen in infancy or childhood.

Alternate names associated with the NP disorder are lipid histiocytosis, sphingomyelin lipidosis, and acid sphingomyelinase deficiency (ASD).

Genetic profile

NP is caused by an autosomal recessive genetic trait; therefore, the condition will not appear unless a person receives the same defective gene for fat metabolism from each parent. This means that if a person is heterozygous (i.e., has two different genes) for the trait, they will be a carrier, and if they are homozygous (i.e., have two of the same mutated genes), they will show the trait. There is a 25% chance for each pregnancy that the disorder will occur in the child(ren) if both parents are heterozygous

Niemann-Pick disease

Definition

Niemann-Pick disease (NP) is a disorder of fat metabolism that causes excessive quantities of lipids (fats) to accumulate in various organs, causing abnormalities of the skin, eyes, musculoskeletal system, nervous system, liver, and lymphoid organs. The disorder is named for German pediatricians Albert Niemann and Ludwig Pick. There are four

for the trait, and a 100% chance if both parents are homozygous for the trait.

NPA and NPB are caused by mutations in the *SMPD1* gene. This gene contains the instructions for making an enzyme called acid sphingomyelinase, which is important in the process of converting a lipid (fat) called sphingomyelin into a different lipid, called ceramide, so that it can be removed from cells. With too little of the enzyme sphingomyelinase, the lipid sphingomyelin accumulates to toxic levels within the cells, which causes cells to die. The death of these cells leads to organ failure, especially in the brain, lungs, liver, and spleen. NPA, which affects the brain, is the most severe type and is usually detected early in infancy. NPB is usually detected in mid-childhood. It does not affect the brain but causes abnormalities in the lungs spleen, and liver.

NPC1 is caused by mutations in the *NPC1* gene, and NPC2 is caused by mutations in the *NPC2* gene. Both genes are important in the production of a protein that helps cells move fats through the cell membrane and out of the cell. Scientists have identified more than 380 different mutations in the *NPC1* gene that can lead to NPC1. When these mutations occur, fat accumulates within the cell, leading to cellular death and causing movement problems, neurological impairment, lung and liver disease, and speech and feeding problems characteristic of NPC1 and NPC2.

Demographics

Niemann-Pick disease affects males and females equally and has been identified in all races. In the general population, it is thought to occur in about one in 250,000 individuals. It is much more common in people of eastern European Jewish descent (Ashkenazi), occurring in about one in 40,000 individuals. As many as one in 75 people in this ethnic group may be carriers of the mutated *SMPD1* gene. NPA is the most common form of the disease and is responsible for about 80% of NP disease cases. NPC1 is much more common than NPC2. NPC2 (formerly called NPD) occurs more often in descendants of French-Canadians (Acadians) from Nova Scotia.

Signs and symptoms

Type A

This is the infantile or acute form of Niemann-Pick disease. Abnormal accumulation of sphingomyelin is seen in the developing fetus. Sphingomyelin accumulation can represent 2% to 5% of the total body weight in individuals with type A. Symptoms may progress rapidly and include the following:

- Hepatosplenomegaly. Enlargement of the liver and spleen is due to the low levels of the enzyme

KEY TERMS

Allele—One of a pair of genes.

Hepatosplenomegaly—Enlargement of the liver and spleen.

Heterozygous—Having two different alleles for a genetic trait.

Homozygous—Having two identical alleles for a genetic trait.

Macula—Abnormal pigmentation in the tissue of the eye.

Sphingomyelin—A group of sphingolipids containing phosphorus.

Sphingomyelinase—An enzyme needed to break down sphingomyelin into ceramide.

sphingomyelinase, which is needed to break down sphingomyelin in the body. The decreased levels of this enzyme cause the sphingomyelin content of the liver and spleen to be abnormally high. Hepatosplenomegaly occurs between the ages of six and 12 months. Occurrence of liver enlargement is seen more commonly than that of the spleen.

- Musculoskeletal abnormalities. Degenerative muscle weakness and floppiness may occur due to a decline in motor and intellectual functioning. The cause is increased accumulation of sphingomyelin in the nervous system. Seizures and muscular spasms may also occur.
- Macula. Pigmentation in the tissue of the eyes may occur. Formation of cherry-red spots may be seen in approximately 50% of patients diagnosed with NPA. This is not visible and can only be detected by using special instrumentation.
- Additional abnormalities. These include jaundice, fever, and gastrointestinal (GI) problems such as vomiting, diarrhea, and abdominal distention.

Type B

This is the chronic form of Niemann-Pick disease. Symptoms progress slowly and begin during infancy through mid-childhood. Like type A, type B occurs due to a deficiency of the enzyme sphingomyelinase. Neurological involvement is minimal and usually absent. Symptoms are as follows:

- Hepatosplenomegaly. Abnormal enlargement of the liver and spleen occur due to the accumulation of sphingomyelin.

- **Macula.** The formation of cherry-red spots on the eyes may be seen in some affected individuals.
- **Additional abnormalities.** These include a slow growth rate and increased incidence of respiratory infections.

Type C1 and C2

These types of Niemann-Pick disease occur due to the inability of the body to break down cholesterol. This leads to a secondary deficiency of acid sphingomyelinase. The signs and symptoms of NPC1 and NPC2 are similar. They can develop at any time between infancy and adulthood but are usually seen in children between the ages of three and ten. The progression of symptoms in NPC1 and NPC2 are slow, and the losses of mental and motor function usually occur in early adulthood. Symptoms are as follows:

- **Hepatosplenomegaly.** The liver and spleen may be moderately enlarged due to the inability to break down cholesterol.
- **Musculoskeletal.** Psychomotor dysfunction, seizures, tremors, and spasticity of the muscles result due to excessive accumulation of cholesterol in the brain. An individual with NPC1 or NPC2 may also exhibit extreme muscle weakness due to emotional excitement and ataxia, which is the inability to coordinate voluntary muscle movements.
- **Eyes.** Both types of NPC are characterized by vertical gaze palsy. This results in the difficulty or loss of up-and-down movement. Some individuals may experience ophthalmoplegia (loss of muscle ability to move eyes). This is an impaired function of the muscles of the eyes and may cause the eyes to become stuck or fixed in an upward position.
- **Additional abnormalities.** These include dysarthria and jaundice. Dysarthria is the inability to form and speak words clearly. Jaundice is a yellow discoloration of the skin, the eyes, and possibly the mucous membranes.

Previously, there were three more identified types of Niemann-Pick disease: types D, E, and F. Researchers discovered that type D is actually a subset of NPC1 with the same genetic mutations. Niemann-Pick disease types E and F are rare and not well defined and are no longer used as diagnostic terms.

Diagnosis

Diagnosis of all types of NP is assisted by taking a detailed family history and a thorough examination of the individual. NPA and NPB are diagnosed through DNA testing or by a blood test. Blood tests for individuals with types A and B will show low levels of the enzyme sphingomyelinase in white blood cells and elevated sphingomyelin and free cholesterol. NPC1 and NPC2 can be diagnosed

QUESTIONS TO ASK YOUR DOCTOR

- How do the various types of Niemann-Pick disease differ from each other?
- How are each of these types of the disorder diagnosed?
- In what ways, if at all, is the treatment of Niemann-Pick dependent on the type of the disorder my child has?
- Are there groups interested in Niemann-Pick disease that can provide additional information and counseling about this condition?

by prenatal testing of fibroblastic cells to determine their ability to process and store cholesterol. This is done by testing the amniotic fluid (liquid that bathes and cushions the fetus). Formation of foam cells occurs in all types of Niemann-Pick disease and can be determined through a biopsy of bone marrow tissue.

Symptoms of Niemann-Pick disease may be similar to those of Refsum syndrome (a disorder of fat metabolism associated with abnormal accumulation of phytanic acid in the blood and other body tissues), Tay-Sachs disease (a disorder found in Eastern European Jewish descendants that results in deterioration of the central nervous system), Sandhoff disease (a lipid-storage disorder due to a deficiency of the enzyme hexosaminidase), Gaucher's disease (a lipid-storage disease), and sialidosis (a metabolic disorder due to a deficiency of the enzyme alpha-neuraminidase).

Treatment and management

There is no specific treatment available for any type of Niemann-Pick disease; however, as of 2021, phase 3 clinical trials of a drug are underway to treat NPC1. The drug is a formulation of hydroxypropyl beta cyclodextrin (Trappsol Cyclo). It is manufactured by Cyclo Therapeutics and has received orphan drug status. The drug is given intravenously. Participation in a clinical trial is voluntary and at no cost to the participant. All clinical trials receiving U.S. government funding, and some supported by private industry, are posted at <https://www.clinicaltrials.gov>. Foreign trials are listed at <https://www.orpha.net>

Until therapeutics become available to treat the various types of NP disease, individuals are treated on a symptomatic basis. People who are diagnosed with NPA and NPB have not benefited from enzyme-replacement therapies or organ transplants. Cholesterol-lowering

drugs and low-cholesterol diets are often used for individuals with NPC1 and NPC2.

Prognosis

The prognosis for all types of Niemann-Pick disease varies. In type A, death usually occurs in early childhood. In individuals with types C1 and C2, death usually occurs in adolescence or early adulthood. Individuals with type B have a prolonged survival rate due to the decrease of neurological involvement. Early diagnosis is important. Due to advances in medicine, an early diagnosis may increase life expectancy.

Affected individuals and their families may want to seek genetic counseling. Pregnant women can receive prenatal testing for some of the gene mutations that cause NP disease. Pregnant women who are likely carriers and have partners who are likely carriers should receive genetic counseling regarding the 25% chance of their child having NP disease.

Niikawa-Kuroki syndrome see **Kabuki syndrome**

Nijmegen breakage syndrome

Definition

Nijmegen breakage syndrome (NBS) is a condition in which chromosomes are susceptible to breakage. Symptoms include short stature, small head size, and increased risk for learning disabilities/intellectual disability, infections, and cancer.

Description

Nijmegen breakage syndrome gets its name from the fact that the first patient was described in Nijmegen in the Netherlands; a registry of patients is maintained there. Patients with the syndrome are susceptible to having their chromosomes break. These breaks result in rearrangements of chromosomes called translocations, in which two chromosomes exchange pieces, and inversions, in which a section of a chromosome breaks off and rejoins the chromosome upside down. Chromosome rearrangements in NBS most commonly involve chromosomes 7 and 14. Genes involved in the immune system are located on these chromosomes; as a result of disruptions of these genes, most patients with NBS have an increased rate of infections, particularly those involving the respiratory system and the urinary tract. The chromosome breaks also increase susceptibility to cancer. People with NBS are more prone to chromosome breaks when exposed to radiation as well. Other defining features of NBS are short stature and small head size.

Genetic profile

NBS is an autosomal recessive disease, which means that one abnormal gene from each parent must be inherited to develop symptoms. A person with only one defective gene copy is called a carrier and will not show signs of NBS but has a 50% chance of passing along the gene to offspring with each pregnancy. Couples in which both parents are carriers of NBS have a 25% chance in each pregnancy of conceiving an affected child. The gene for NBS is on chromosome 8 and is called the *NBS1* gene, coding for a protein called nibrin, which is found in all cells throughout the body. Normal nibrin is believed to be important in the repair of DNA that has been damaged by breaks in both strands.

Most patients have a specific change in both copies of the nibrin gene in which a string of five DNA bases, ACAA, is missing from a specific area of the gene, leading to a shortened, or truncated, version of nibrin. A few other mutations have been reported in single patients.

All of these mutations also result in a shortened, nonfunctional version of nibrin.

Demographics

NBS is extremely rare. Approximately 150 patients have been reported in medical literature. Most patients have been of Slavic or other European descent, with a few patients reported from New Zealand, Mexico, and the United States.

Signs and symptoms

Virtually all patients with NBS have microcephaly, or a small head size (in the lower 3%), with about 75% having this feature present at birth. Young children with NBS show impaired growth. Babies with NBS are either born small or begin to experience growth delay during their first two years. The growth rate is normal after that, but the children always remain small for their ages. According to data available, approximately 40% have normal intelligence, 50% have borderline to mild intellectual disability (IQ of 55 to 70), and 10% have moderate intellectual disability (IQ of 40 to 54). There is a characteristic facial appearance, which includes a receding forehead, long nose, receding chin, extra folds of skin underneath the eyes, freckles on the nose and cheeks, large ears, and thin hair. Patients frequently have café-au-lait spots (areas of skin that are the color of coffee with milk), and other pigment changes in the skin and eyes.

The incidence of certain birth defects is increased in NBS, with about half of patients having malformed fingers or extra skin between the fingers (called syndactyly). A few patients have been reported to have anal malformations, lack of development of the ovaries and consequent infertility, hip abnormalities, and bone, kidney, and brain abnormalities. Notably lacking is the ataxia, which is progressive loss of coordination, seen in a disorder called ataxia-telangiectasia (A-T), which is otherwise very similar to NBS but is caused by a mutation in a different gene.

People with NBS are at increased risk for infections, most commonly affecting the respiratory tract and urinary tract. Infections of the gastrointestinal tract have also been reported. They are also at increased risk for cancer, mostly B cell lymphoma. Leukemia and other cancers have also been reported.

Diagnosis

A diagnosis of NBS is suspected in children with small head size, slow growth at birth, characteristic facial features including a receding chin and prominent nose,

KEY TERMS

Balanced chromosome translocation—A rearrangement of the chromosomes in which two chromosomes have broken and exchanged pieces without the loss of genetic material.

Chromosome inversion—Rearrangement of a chromosome in which a section of a chromosome breaks off and rejoins the chromosome upside down.

Microcephaly—Abnormal smallness of the head; it is often associated with intellectual disability.

recurrent infections, cancer (particularly B cell lymphoma), and borderline to moderate intellectual disability. Prior to the discovery of the nibrin gene, diagnosis could only be confirmed by studying the levels of immune system proteins called immunoglobulins, looking for particular chromosomal changes involving chromosomes 7 and 14, and assessing radiation sensitivity in cells from patients.

The gene for NBS was discovered in 1998, so it is now possible to look for a mutation in a patient's nibrin gene. If a mutation other than the common one is found, it is important to do further investigation to determine whether or not it causes disease, as non-disease-causing changes have been reported in the nibrin gene.

Adults who are at risk for having children with NBS, such as siblings of patients, can have carrier testing to determine if they have one altered nibrin gene and are carriers for NBS. During pregnancy, the DNA of a fetus can be tested using cells obtained using the procedures called chorionic villus sampling (CVS), in which cells from the placenta are studied, or amniocentesis, in which skin cells from the amniotic fluid surrounding the baby are tested.

Treatment and management

There is no specific treatment for NBS, although folic acid (a vitamin B derivative) is recommended for prevention of chromosome breaks, since repair of these breaks is compromised in NBS. Similarly, vitamin E is recommended for prevention of further cell damage. For treatment of cancer, high doses of radiation must be avoided, since the damage inflicted on the cells could be fatal. Research studies in 2015 provided proof of concept studies in mice for the use of antisense oligonucleotides as a potential cancer prophylaxis for patients with NBS.

QUESTIONS TO ASK YOUR DOCTOR

- To what does the term “breakage” refer in the name of this disorder?
- Is there a way to prevent the occurrence of Nijmegen breakage syndrome in our future children?
- How common is Nijmegen breakage syndrome in the United States and worldwide?
- What medical problems are typically associated with this condition?

Prognosis

Patients with NBS have a decreased lifespan because of the tendency toward infection and cancer. Most patients do not survive past 30–40 years of age.

Noack syndrome see **Pfeiffer syndrome**

Noninvasive prenatal screening

Definition

Noninvasive prenatal screening (NIPS) is an assay or blood test given to a pregnant woman to estimate the risk that the unborn child has a chromosome disorder. It is also known as noninvasive prenatal testing (NIPT), the cell-free fetal DNA test, or the cell-free DNA prenatal screen for fetal aneuploidy, its formal name. *Aneuploidy* is the medical term for an abnormal number of chromosomes in a cell, whether extra or missing chromosomes.

Purpose

The most common reason for performing NIPS is to screen the fetus during the first trimester of pregnancy for an increased risk of three trisomies (chromosome disorders in which there are three copies of specific chromosomes): trisomy 13 (Patau syndrome); trisomy 18 (Edwards syndrome); and trisomy 21 (Down syndrome). While Down syndrome is the most common trisomy, its symptoms vary considerably in severity. Some children with the syndrome are able to finish high school and find employment with accommodation. On the other hand, about 90% of children born with Patau syndrome or Edwards syndrome die within a year after birth.

A version of NIPS called genome-wide NIPS can be used to screen all 23 sets of human chromosomes; thus, it can screen for disorders of the sex chromosomes, which also means that it can be used to identify the child's sex before birth. Genome-wide NIPS can also be used to screen for microdeletion syndromes, which are a group of disorders characterized by the loss of small segments of DNA from specific chromosomes. With the exception of DiGeorge syndrome, caused by a microdeletion on chromosome 22 at 22q11.2 that leads to the loss of 30 to 40 genes, most microdeletion syndromes are quite rare.

In addition, it is not clear as of 2021 whether present genome-wide versions of NIPS are as effective in identifying microdeletions as more widely recognized types of diagnostic testing. Researchers at Harvard University reported in March 2021 that genome-wide NIPS does not detect clinically significant chromosomal abnormalities at the same rate as chromosomal microarray (CMA) testing. CMA testing is a procedure in which samples of DNA from the patient and a control subject are labeled with two different fluorescent substances, then mixed and allowed to bind (hybridize) to short fragments of synthetic DNA, known as probes, on the surface of the microarray (a glass or plastic chip). The chip can then be analyzed to see whether the patient's DNA binds to

Noninvasive prenatal testing. (Shutterstock/rumruay)

sequences on the chip representing normal DNA or whether it binds to sequences containing a microdeletion.

Precautions

There are several precautions to keep in mind regarding NIPS. First of all, although the procedure is sometimes called a noninvasive prenatal test or NIPT, it is *not* a diagnostic test; it can only assess whether the risk of a chromosomal aberration is high or low. This characteristic means that NIPS can yield both false positives (indicating that the fetus has an abnormality when in fact it does not) and false negatives (indicating that genetic abnormalities are not present when they actually are). For this reason, genetic counselors and gynecologists recommend that a positive result from NIPS be followed up by an invasive diagnostic test like amniocentesis or chorionic villus sampling to confirm the positive finding.

A second precaution in regard to NIPS is that the accuracy of the test is affected by its timing (number of weeks of gestation) and by the patient's body mass index (BMI). Because NIPS analyzes cell-free fetal DNA (cffDNA) that is circulating in the patient's bloodstream, there must be a sufficient quantity of this type of DNA to yield reliable results. Cell-free fetal DNA is present in the mother's blood when the bloodstream contains both material from the placenta and cell-free DNA from the mother herself. The proportion of cell-free DNA that comes from the placenta is called the fetal fraction, and it should be above 4% for best results. The fetal fraction does not usually reach this level until the tenth week of pregnancy, and it is also inversely proportionate to the mother's weight. If the fetal fraction is too low, it may mean that the sample was taken too early; that the mother is obese; or that the fetus is abnormal.

A third precaution is the need for counseling if the results of the screening test are positive and/or if the determination of the baby's sex is problematic for the parents. Since NIPS was introduced by private health care providers in 2011, it has been introduced in some countries by public health care services, partly because of its noninvasiveness and partly because of its relatively low expense. Its increased use means, however, that growing numbers of people from countries with widely varying ethical attitudes toward pregnancy termination are confronted with difficult decisions. In some countries, most notably Germany, policy debates about the provision of public health insurance for NIPS are heated because of concerns about reviving the eugenic practices of the Nazi era (1933–1945), during which children with genetic disorders were euthanized. In other countries, the possibility of using NIPS for prenatal sex selection is worrisome because of a strong popular preference for male children. As a result, health care providers in most countries urge patients to undergo follow-up diagnostic testing along with consultation with their gynecologist and a genetic counselor before making a decision about the pregnancy on the basis of NIPS screening alone.

Description

NIPS is done by a simple blood draw from the patient's arm. After the sample is taken, it is sent to a laboratory for measurement of the fetal fraction and evaluation of the cell-free fetal DNA contained in the sample. It takes about a week for the results of the screening test to be reported to the patient's doctor.

Preparation

No physical preparation is needed for the blood draw. However, even though NIPS is a standard

KEY TERMS

Amniocentesis—A diagnostic procedure in which a small sample of amniotic fluid is withdrawn from the uterus of a pregnant woman through a needle inserted in the abdomen. The fluid is then analyzed to detect genetic abnormalities in the fetus or to determine fetal sex.

Aneuploidy—An abnormal number of chromosomes in a cell, whether extra or missing chromosomes.

Assay—A laboratory test designed to identify and measure the amount of a specific substance.

Base pair (bp)—Any of the complementary nucleotide bases (adenine-thymine and cytosine-guanine in DNA; adenine-uracil and cytosine-guanine in RNA) held together by weak hydrogen bonds. Base pairs form links between the two strands of DNA.

Body mass index (BMI)—A measure of body fat derived from a person's height and weight. It is calculated by taking the person's weight in kilograms and dividing by the square of the person's height in meters.

Chorionic villus sampling (CVS)—An invasive diagnostic test for genetic disorders in which a small sample of cells is taken from the placenta of a pregnant woman, either through the cervix or through the abdominal wall for testing.

Chromosomal aberrations—A general term for abnormalities in either the number or the structure of chromosomes.

Chromosomal microarray (CMA) testing—A prenatal genetic test used to diagnose microdeletion syndromes and some aneuploidies. It consists of DNA samples from the patient and a reference source that have been labeled with fluorescent dyes and allowed to hybridize or bind to the synthetic DNA on the glass or plastic chip. The chip is then scanned by a computer to determine whether the patient's DNA binds to the normal DNA sequence or whether it binds to the sequence representing a DNA mutation.

Ethics—The branch of philosophy dealing with questions of good and evil, and with moral duties and obligations in human society.

Eugenics—A set of beliefs and practices intended to improve the genetic quality of a country's human population, either by limiting the reproduction of people considered unfit or by encouraging the reproduction of healthier, more intelligent, and more attractive people.

False negative—A test result that indicates that a disease or condition is not present when it really is; sometimes called a type II error.

False positive—A test result that indicates that a person has a disease or condition when they do not; it is sometimes called a type I error.

Fetal fraction—The proportion of cell-free DNA in a pregnant woman's blood that comes from the placenta. The fetal fraction should be above 4% for the most accurate results.

Genome—The total amount of genetic information within an organism's chromosomes, including its genes and DNA sequences.

Microdeletion—A chromosome deletion that is too small to be detected by standard karyotyping methods. Microdeletions are typically one to three mega bases in length (one to three million base pairs), whereas standard deletions are five mega bases or longer.

Nuchal—Referring to the nape of the neck.

Phlebotomist—A nurse or other health care worker with special training in drawing venous blood for testing or analysis.

Placenta—An organ that develops in humans and other mammals during pregnancy that lines the wall of the uterus and is attached to the fetus by the umbilical cord. It is sometimes called the afterbirth because it is expelled from the uterus after the baby is delivered.

Trisomy—A type of aneuploidy in which there are three copies of a specific chromosome in cells instead of the normal two. Genetic disorders caused by trisomies include Down syndrome (trisomy 21) and Edwards syndrome (trisomy 18).

procedure offered to pregnant women in the United States as of 2021, the patient should discuss the screener with her gynecologist before the test to be sure she understands why it is recommended and whether it is the right test for her. Some laboratories offer patients

a choice about screening for sex chromosome abnormalities and/or microdeletion syndromes in addition to the standard aneuploidies, and the patient should consider whether she prefers to opt in or opt out for this information.

QUESTIONS TO ASK YOUR DOCTOR

- What is your opinion of NIPS as a genetic screening test?
- Do you recommend it to your pregnant patients?
- What advice or counseling do you give patients before the test?
- Do you think that future versions of NIPS will be able to screen for a wider range of genetic disorders?

Aftercare

Aftercare for NIPS is the same as for any other blood test; the nurse or phlebotomist applies a clean dressing over the location of the venipuncture. The patient is asked to apply gentle pressure for a few seconds to help the blood clot and to keep the dressing on the arm for a few hours.

Risks

One reason why NIPS is increasingly recommended to patients is that it carries no risk to the pregnancy, in contrast to invasive diagnostic tests. There are few risks to the blood test itself. Some patients may experience swelling or minor bruising at the site of the venipuncture, but applying ice to the area or taking an over-the-counter pain reliever is all that is usually needed. The risk of infection is very low.

Results

The result of a NIPS test are given as positive or increased/high risk; negative or low risk; and indeterminate or “no call.” A positive result means that the fetus has a higher chance of having the chromosomal abnormality in question; it does not mean that the fetus definitely has the abnormality. Similarly, a negative result does not mean that the fetus does not have the chromosomal abnormalities being tested for, only that the risk is lower.

An indeterminate or “no call” finding may mean that the test was performed too early in the pregnancy, before there was enough cffDNA in the mother’s blood to be detected in the test. It can also mean that the mother’s weight has affected the test results, as obese women have a lower proportion of cffDNA in their blood. Last, an indeterminate finding is more likely if the mother is carrying twins or triplets.

Gynecologists generally recommend an invasive diagnostic test like amniocentesis or chorionic villus sampling, rather than repeating NIPS, if the test results are indeterminate.

Alternatives

Alternatives to NIPS for first-trimester genetic screening include:

- **Maternal blood serum screening.** The mother’s blood can be measured for pregnancy-associated plasma protein A (PAPP-A) and for human chorionic gonadotropin (hCG), a hormone that is important in the early stages of pregnancy. Low levels of PAPP-A and high levels of hCG indicate an increased risk that the fetus has Down syndrome.
- **Nuchal transparency measurement.** Nuchal transparency refers to a clear space at the back of the baby’s neck that can be detected by ultrasound. An enlargement of this space (greater than the 99th percentile for the fetus’s gestational age) indicates an increased risk of Down syndrome.

Another option is to wait until the second trimester of pregnancy and perform the following screening tests:

- **Maternal blood serum screening.** In the second trimester, this test will include measurements of alpha-fetoprotein, human chorionic gonadotropin, and unconjugated estriol (a female sex hormone whose levels are increased during pregnancy), which is called a triple screen. If inhibin A (a protein complex that can be used to screen for Down syndrome) is also measured, the test is called a quad screen.
- **Integrated screening.** In integrated screening, the results of first-trimester screening tests are combined with the findings of second-trimester tests.

If any of these screening tests yields a positive result, indicating an increased risk of a chromosomal disorder, gynecologists recommend offering the patient diagnostic testing by CVS or amniocentesis.

Research

There are 56 clinical trials of NIPS registered with the NIH as of mid-2021, in countries including France, Denmark, the United Kingdom, Sweden, Belgium, Italy, and Turkey as well as the United States and Canada. Some of these trials are evaluating the accuracy of NIPS in detecting single-gene (monogenic) disorders or micro-deletion syndromes, while other trials are concerned with evaluating patients’ access to NIPS, their responses to the test, or designing modified versions of NIPS to be used in screening multiple pregnancies.

Noonan syndrome

Definition

Noonan syndrome is a relatively common genetic condition with a wide range of symptoms. People with Noonan syndrome can have many different features, but the most common are unique facial features, a heart defect at birth and/or heart problems later in life, short stature, a broad or webbed neck, chest deformities, and intellectual disability.

Description

Noonan syndrome was first described by the pediatrician and heart specialist Jacqueline Noonan in 1963. It is part of a group of conditions that are caused by pathogenic variants (mutations) in genes in the RAS-MAPK pathway, which allows cells to communicate and affects processes like cell growth and death. This group of conditions, including Noonan syndrome, are sometimes called RASopathies. There can be overlap in symptoms between Noonan syndrome and different RASopathies, which can sometimes make the diagnosis difficult. Since Noonan syndrome can be caused by variants in many different genes, it can cause a wide range of symptoms, and different individuals often have different combinations of characteristics. A diagnosis of Noonan disease is usually first made through examination of clinical features, detailed physical examination, and family and medical history. The next step is usually genetic testing. About 20 out of 100 people with this condition (20%) do not have a known gene variant, since not all variants have been discovered.

Genetic profile

Noonan syndrome can be caused by variants (mutations) in over 20 genes. Nine genes involved in the RAS-MAPK pathway are known to be associated with 70% to 85% of patients with Noonan Syndrome. These genes are PTPN11 (responsible gene for 50% of patients), SOS1, KRAS, NRAS, BRAF, RAF1, MAP2K1, CBL, and SHOC2.

In most cases, Noonan syndrome is inherited in an autosomal dominant manner. This means that an affected individual has one copy of the gene variant and has a 50% chance of passing it on to their male or female children. About half of people with Noonan syndrome have a family history of it. For the other half, the gene variant likely occurred as a new event in their conception, which means that they were the first person in their family to be diagnosed with the condition. The person with this new

mutation would have a 50% chance of passing it on to their children.

In some rare cases, Noonan syndrome can be inherited in an autosomal recessive manner. For example, there have been at least 12 families with variants in the LZTR1 gene that appear autosomal recessive. In those families, the parents of affected children have a variant in one copy of the LZTR1 gene but do not have any symptoms. Their children with Noonan syndrome all had variants in both copies of the LZTR1 gene, which they inherited from both parents. The parents are considered silent carriers, since they do not have any symptoms, which is fairly common in autosomal recessive conditions. With this type of inheritance, only parents who are both carriers of variants in the same gene can have an affected child. Two carriers have a 25% chance of having an affected male or female child. Parents who are blood-related are more likely to have a child with a recessive condition, since they are more likely to have similar gene variants.

Demographics

Noonan syndrome occurs in between one in 1,000 and one in 2,500 live births. It does not seem to be more likely to affect a certain ethnicity, although many studies have been done in only a few countries such as the Netherlands, Canada, and the United States.

Signs and symptoms

Symptoms of Noonan syndrome are common at birth. People with Noonan syndrome are often born with heart defects. Pulmonary stenosis, which causes a blockage of flow of blood, resulting from a narrowing in part of the heart, is the most common heart defect. Muscle weakness is sometimes present, as is increased flexibility of the joints. Occasionally, feeding problems may occur

Ultrasound showing a cardiac deformity as the result of Noonan syndrome. (Dr. Darsin/Science Source)

KEY TERMS

Amniocentesis—A procedure performed at 16 to 18 weeks of pregnancy, in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Café-au-lait spots—Birthmarks that may appear anywhere on the skin; named after the French coffee drink because of the light-brown color of the marks.

Cryptorchidism—A condition in which one or both testes fail to descend normally.

Cystic hygroma—An accumulation of fluid behind the fetal neck, often caused by improper drainage of the lymphatic system in utero.

Karyotype—A standard arrangement of photographic or computer-generated images of chromosome pairs from a cell in ascending numerical order, from largest to smallest.

Neurofibromatosis—A progressive genetic condition often including multiple café-au-lait spots, multiple raised nodules on the skin known as neurofibromas, developmental delays, slightly larger head sizes, and freckling of the armpits, groin area, and iris.

Nystagmus—Involuntary, rhythmic movement of the eye.

Pectus carinatum—An abnormality of the chest in which the sternum (breastbone) is pushed outward. It is sometimes called "pigeon breast."

Pectus excavatum—An abnormality of the chest in which the sternum (breastbone) sinks inward; sometimes called "funnel chest."

Phenotype—The physical expression of an individual's genes.

Pterygium colli—Webbing or broadening of the neck, usually found at birth and usually on both sides of the neck.

Pulmonary stenosis—Narrowing of the pulmonary valve of the heart, between the right ventricle and the pulmonary artery, limiting the amount of blood going to the lungs.

Strabismus—An improper muscle balance of the ocular muscles resulting in crossed or divergent eyes.

Suture—"Seam" that joins two surfaces together.

Turner syndrome—Chromosome abnormality characterized by short stature and ovarian failure, caused by an absent X chromosome. Occurs only in females.

in infants with Noonan syndrome, because of a poor sucking reflex. Short stature by adulthood is common, though birth length is typically normal. Developmental delays may become apparent, because individuals are slower to attain milestones, such as sitting and walking. Behavioral problems may be more common but often are not significant enough for medical attention.

Many facial features are found in Noonan syndrome, often involving the eyes. Eyes may be wide-set or may appear half-closed because of droopy eyelids, and the corners may turn downward. Some other findings, such as nystagmus and strabismus, may occur. Interestingly, most people with Noonan syndrome have pale blue- or green-colored eyes. Often, the ears are low-set (lower than eye-level), and the top portion of cartilage on the ear is folded down more than usual. Hearing loss may occur, most often due to frequent ear infections. A very high and broad forehead is common. An individual's face may take on an inverted triangular shape. As mentioned earlier, facial features may change over time. An infant with the syndrome may appear more striking than an

adult who has it, as the features may gradually become less obvious. Sometimes, studying childhood photographs of an individual's presumably "unaffected" parents may reveal clues. Parents may have more obvious features of the condition in their childhood photographs.

Chest wall abnormalities, such as a shield chest, pectus carinatum, and pectus excavatum, occur in the majority of people with NS1. These are thought to occur because of early closure of the sutures underneath these areas. Additionally, widely spaced nipples are not uncommon. Scoliosis (curving of the spine) may occur, along with other spine abnormalities.

Lymphatic abnormalities may be common, often due to abnormal drainage or blockage in the lymph glands. This may cause lymphedema, or swelling, in the limbs. Lymphedema may occur behind the neck (often prenatally), and this is thought to be the cause of the broad/webbed neck in the condition. Prenatal lymphedema is thought to obstruct the proper formation of the ears, eyes, and nipples as well, causing the mentioned abnormalities in all three.

Individuals with Noonan syndrome may have problems with coagulation, shown by abnormal bleeding or mild-to-severe bruising. Von Willebrand disease and abnormalities in levels of factors V, VIII, XI, XII, and protein C (all proteins involved in clotting of blood) are common, alone or in combination. These problems may lessen as the person ages, even though the mentioned coagulation proteins may still be present in abnormal amounts. Rarely, some forms of leukemia and other cancers occur.

Kidney problems are often mild but can occur in patients with Noonan syndrome. The most common finding is a widening of the pelvic (cup-shaped) cavity of the kidney. In males, smaller penis size and cryptorchidism are sometimes seen. Cryptorchidism may lead to improper sperm formation in these men, although sexual function is typically normal. It is not as common to see an affected man have a child with Noonan syndrome, and this is probably due to cryptorchidism. Puberty may be delayed in some women with NS1, but fertility is not usually compromised.

Lastly, follicular keratosis is common on the face and joints. It is a set of dark birthmarks that often show up during the first few months of life, typically along the eyebrows, eyes, cheeks, and scalp. Generally, it progresses until puberty and then stops. Sometimes, it may leave scars, which may prevent hair growth in those areas. Café-au-lait spots can occur, not unlike those seen in neurofibromatosis.

Diagnosis

Diagnosing Noonan syndrome comes from a clinical diagnosis, based on findings and symptoms. Genetic testing can help diagnose this syndrome. One challenge faced in the diagnosis of Noonan syndrome is that there are several conditions that mimic it. If a female has symptoms, a chromosomal study is crucial to determine whether she has Turner syndrome, as she would have a missing X chromosome. Other chromosomal conditions that are similar include trisomy 8p (three copies of the small arm of chromosome 8) and trisomy 22 mosaicism (mixed cell lines, with some having three copies of chromosome 22). A karyotype would help to rule these out.

Cardio-facio-cutaneous syndrome (CFC) can be confused with Noonan syndrome, since it results in similar facial features, short stature, lymphedema, and developmental delays, as well as similar heart defects and skin findings. These conditions likely have similar features because they both result from gene variants in the same RAS-MAPK pathway. There are other similar conditions that result from variants in genes in the same pathway (for

QUESTIONS TO ASK YOUR DOCTOR

- Are there visual signs by which Noonan syndrome can be diagnosed, and are these signs a sufficient basis for diagnosing the condition?
- What are the most serious medical problems associated with this genetic disorder?
- What information or advice can a genetic counselor provide about the possibility of our having a child with Noonan syndrome?
- Please describe the challenges we would face in the future as the parents of a child with Noonan syndrome.

example, Watson and multiple lentigines/LEOPARD syndrome, which are also associated with pulmonary stenosis, wide-set eyes, chest deformities, and mental delays). Genetic testing can help differentiate conditions resulting from different gene variants on this pathway.

Most individuals are diagnosed with Noonan syndrome in childhood. A diagnosis can sometimes be made during pregnancy, since lymphedema, cystic hygroma, heart defects, and sometimes facial features can sometimes be seen on a prenatal ultrasound. Prenatal testing of the fetus can be done to help make a diagnosis.

Artificial intelligence

Promising research suggests that computers may help diagnose Noonan syndrome. In one study, a computer analyzed pictures of people with and without Noonan syndrome and were able to make an accurate diagnosis 91% of the time. This type of technology may be particularly helpful for Noonan syndrome, which can be difficult to diagnose.

Treatment and management

Treatment is symptom-specific, as not everyone will have the same needs. For short stature, some individuals have responded to growth hormone therapy. The exact cause of the short stature is not well defined, and therapies are currently being studied. Muscle weakness and early developmental delays often necessitate an early intervention program, which combines physical, speech, and occupational therapies. Heart defects need to be closely followed, and treatment can sometimes include beta blockers or surgeries, such as opening of the pulmonary valve. For individuals with clotting problems, aspirin and medications containing it should be avoided, as

they prevent clotting. Treatments using various blood factors may be necessary to help with proper clotting. Drainage may be necessary for problematic lymphedema, but it is rare. Cryptorchidism may be surgically corrected, and testosterone replacement should be considered in males with abnormal sexual development. Back braces may be needed for scoliosis and other skeletal problems. Unfortunately, medications such as creams for the follicular keratosis are usually not helpful. Developmental delays should be assessed early, and special education classes may help. In summary, these various treatment modalities require careful coordination, and many issues last for a patient's entire life. A team approach may be beneficial.

New treatment for heart problems and lymphatic disorders

Promising research suggests that a drug called Trametinib appears to improve the outcome for some infants with Noonan syndrome and heart problems. This drug has been tested on infants who have a variant in the RIT1 gene. Normally, only 34% of these infants survive to one year. This drug also appears to help some people with Noonan syndrome who also have lymphatic disorders.

Prognosis

Prognosis for Noonan syndrome is largely dependent on the extent of the various medical problems, particularly heart defects. Individuals with a severe form of the condition may have a shorter lifespan than those with a milder presentation. In addition, presence of mental deficiency in 25% of individuals affects the long-term prognosis.

Norrie disease

Definition

Norrie disease (ND) is blindness that is evident at birth or within the first few months of life and may involve deafness, intellectual disability, and behavioral problems.

Description

ND was first described in the 1920s and 1930s as an inherited form of blindness affecting only males. Recognizable changes in certain parts of the eye were identified that lead to a wasting-away or shrinking of the eye over time.

At birth, a grayish yellow tumor-like mass is observed to cover or replace the retina of the eye, whereas the remainder of the eye is usually of normal shape, size and form. Over time, changes in this mass and progressive deterioration of the lens, iris, and cornea cause the eye to appear milky in color and become very small and shrunken. ND is always present in both eyes and although some abnormalities in the eye develop later, blindness is often present at birth. Some degree of intellectual disability, behavior problems, and deafness may also occur.

ND is inherited in an X-linked recessive manner, affecting almost only males. The gene for ND was found in the 1990s and genetic testing is available.

ND has also been referred to as the following:

- Norrie-Warburg syndrome
- Atrophia bulborum hereditaria

KEY TERMS

Cataract—A clouding of the eye lens or its surrounding membrane that obstructs the passage of light, resulting in blurry vision. Surgery may be performed to remove the cataract.

Cochlea—A bony structure shaped like a snail shell located in the inner ear. It is responsible for changing sound waves from the environment into electrical messages that the brain can understand, so people can hear.

Cornea—The transparent structure of the eye over the lens that is continuous with the sclera in forming the outermost protective layer of the eye.

Iris—The colored part of the eye, containing pigment and muscle cells that contract and dilate the pupil.

Retina—The light-sensitive layer of tissue in the back of the eye that receives and transmits visual signals to the brain through the optic nerve.

- Congenital progressive oculo-acoustico-cerebral degeneration
- Episkopi blindness
- Pseudoglioma congenita

Genetic profile

ND is an X-linked recessive condition that affects primarily males. Genetic studies of many families led to the identification of the gene *NDP* (Norrie disease protein), which is located at Xp11 that is on the shorter or upper arm of the X chromosome. *NDP* encodes the protein Norrin, whose function is not well understood. Preliminary evidence suggests that norrin plays a role in directing how cells develop to become specialized (differentiation).

Many different kinds of mutations have been described for the *NDP* gene that were thought to lead to ND. The majority of these mutations are called point mutations, which alter just a single unit of the genetic code. Most of the identified point mutations are unique to the type of ND occurring in a family, but the type of point mutation does not seem to determine severity of disease. Other errors that can alter the *NDP* gene are called deletions, which permanently remove a portion of the genetic code from the gene. Individuals with deletions in the *NDP* gene are thought to have more severe forms of ND that usually include profound intellectual disability, seizures, small head size, and growth delays.

The X chromosome is one of the human sex chromosomes. A human being has 23 pairs of chromosomes in each cell of their body. One of each chromosome is inherited from the mother and the other is inherited from the father, making a total of 46 chromosomes. The 23rd pair is the sex chromosome pair. Females have two X chromosomes and males have an X and Y chromosome pair. Females therefore, have two copies of all the genes on the X chromosome but males have only one copy. Mothers pass on either one of their X chromosomes to all of their children, and fathers pass on their X chromosome to their daughters and their Y to their sons.

Males affected with ND have a mutation in the only copy of the *NDP* gene on their X chromosome and cannot make any normal norrin protein. Mothers of such affected males are usually carriers of ND; they have one *NDP* gene with a mutation on one X chromosome and one normal *NDP* gene on the other X chromosome that is sufficient for norrin protein function, so that they do not show signs of ND. Women that are carriers for ND have a 50% chance of passing the disease gene onto each of their children. If that child is male he will be affected with ND; if that child is female she will be a carrier of ND but not affected. Affected males that have children would pass on their disease gene to all of their daughters who would be carriers of ND. Their sons inherit their Y chromosome and would not inherit the gene for ND from their fathers.

Genetic testing for mutations in the *NDP* gene is clinically available to help confirm a diagnosis of ND. As of 2021, this testing is able to identify gene mutations in about 70% of affected males. If such a mutation were found in an affected individual, accurate carrier testing would be available for females in that family. Additionally, diagnosis of a pregnancy could be offered to women who are at risk for having sons with ND.

Demographics

ND has been observed to affect males of many ethnic backgrounds, and no ethnic group appears to predominate. The incidence is unknown, however.

Signs and symptoms

The first sign of ND is usually the reflection of a white area from within the eye, which gives the appearance of a white pupil. This is caused by a mass or growth behind the lens of the eye that covers the retina. This mass tends to grow and cause total blindness. It may also develop blood vessels that may burst and further damage the eye. At birth the iris, lens, cornea, and globe of the eye are generally otherwise normal. The problems in the retina develop over the first few months and until about

QUESTIONS TO ASK YOUR DOCTOR

- Are there medical problems other than vision loss associated with Norrie disease?
- Are there prenatal tests or other procedures by which Norrie disease can be diagnosed in our child?
- What types of medications, surgical procedures, or other procedures are recommended for the care of a child with Norrie disease?
- What associations or agencies assist parents and children with Norrie disease?

10 years of age progressive changes in other parts of the eye can also occur. Cataracts form, and the iris can stick or become attached to the cornea and/or the lens of the eye. The iris will also often decrease in size as ND impairs the development and growth of the eye. Pressure in the fluid within the eye may increase, which can be painful. The retina often becomes detached and may thicken. Toward the end stages of the disease, the eye globe is seen to shrink considerably in size and appear sunken within the eye socket. In cases of ND both eyes are usually affected, and the changes are usually the same in each eye.

Approximately 50% of affected males have some degree of developmental delay or intellectual disability. Some may show behavioral problems or psychosis-like features. Hearing loss may develop in 30%–40% of males with ND starting in early childhood. If speech is developed before the onset of deafness, it is usually preserved. Mental impairment and hearing loss do not necessarily occur together. The role that the norrin protein plays in causing mental impairment and hearing loss is unknown.

The symptoms associated with ND are diverse within a family as well as between families. On rare occasions, carrier females may show some of the retinal problems, such as retinal detachment, and may have some degree of vision loss.

Diagnosis

The diagnosis of ND is usually made by clinical examination of the eye by an ophthalmologist. Gene testing can be pursued as well, keeping in mind that as many as 30% of affected males cannot be identified using current methods.

The symptoms of ND have considerable overlap with a few other eye diseases, and ND must be distinguished from other eye conditions:

- Persistent hyperplastic primary vitreous (PHPV)
- Familial exudative vitreoretinopathy (FEVR)
- Retinoblastoma (RB)
- Retinopathy of prematurity (ROP)
- Incontinentia pigmenti type 2 (IP2)

PHPV and FEVR have been shown to be associated with mutations in the *NDP* gene and may represent a more mild condition in the broad spectrum of ND.

Treatment and management

Since the symptoms of ND are often present at birth, little can be done to change them or prevent the disease from progressing. If the retina is still attached to the back of the eye, surgery or laser therapy may be helpful. An ophthalmologist should follow all children with ND to monitor the changes in the disease, including the pressure within the eye. Occasionally surgery may be necessary, and rarely the eye is removed because of pain.

The child's hearing should also be monitored regularly so that deafness can be detected early. For individuals with hearing loss, hearing aids are usually quite successful. Cochlear implants may be considered when hearing aids are not helpful in restoring hearing.

Developmental delays or intellectual disability, as well as lifelong behavioral problems, can be a continuous challenge. Educational intervention and therapies may be helpful and can maximize a person's educational potential.

Prognosis

The lifespan of an individual with ND may be within the normal range. Risks associated with deafness, blindness, and intellectual disability, including injury or illness, might shorten the lifespan. General health, however, is normal.

Nucleic acid therapies

Definition

Nucleic acid therapies treat disease through the use of nucleic acids such as DNA and RNA or closely related chemicals. They work by inhibiting the function of a particular gene or through adding, replacing, or editing of a gene.

Description

DNA, RNA, and the creation of proteins

In order to better understand nucleic acid therapies it is necessary to understand DNA and RNA along with how they work together to make proteins.

Deoxyribonucleic acid (DNA) is a molecule that contains the instructions for building and maintaining an organism. Most DNA is found in the cell nucleus. The instructions are stored in the DNA as a sequence of bases: adenine (A), cytosine (C), guanine (G), and thymine (T). A three-base sequence in the DNA contains the instructions for making a particular amino acid. For example, CGC codes for the amino acid alanine. Proteins are made up of one amino acid or several amino acids strung together. Proteins are the building blocks of life. They

guide the development and functioning of the body. The sequence of DNA that contains the instructions for a particular protein is a gene.

The DNA molecule is double stranded, and the two strands join together to form a spiral that looks a little like a twisting staircase. Each step of the staircase is made from the pairing of two bases: (A) pairs with (T) and (C) pairs with (G). These are called base pairs.

In order for a protein to be produced, the DNA sequence that contains a gene needs to be transcribed into a single-stranded molecule called messenger RNA (mRNA). Generally one gene on the DNA is transcribed to one mRNA molecule, making one protein. The RNA sequence will match the DNA sequence, except that when (T) is found on the DNA sequence it will be replaced by uracil (U) in the RNA sequence.

The translation of mRNA into proteins occurs in the ribosome, a complex molecule made of RNA and proteins that acts like a protein synthesis factory. At the start of protein synthesis, the ribosome binds to the start of the mRNA. The ribosome recognizes the start of the mRNA, since all mRNA molecules start with the sequence AUG.

A transfer RNA molecule (tRNA), carrying the amino acid methionine, will bind to the complementary AUG sequence and start the chain of amino acids with methionine. The mRNA sequence will continue to be translated by the ribosome with tRNA molecules bringing the correct amino acids and adding them to the growing chain. The creation of the chain of amino acids (protein) continues until the ribosome reaches a stop sequence (UAA, UAG, and UGA). The ribosome recognizes that this is the end of the protein sequence since there are no tRNA molecules that are complementary to this sequence. The new protein is released, and the mRNA ribosome complex comes apart.

Types of nucleic acid therapies

Although the storage of genetic information and the creation of proteins are important functions of DNA and RNA, these molecules have other functions. Thus they are good therapeutic targets. Nucleic acid therapies work by inhibiting the function of a particular gene or through adding, replacing, or editing of a gene. These types of therapies are potentially effective because they have long-lasting effects and even sometimes provide a cure.

Potential challenges with these therapies include the following issues:

- how to deliver the therapy
- how to mass production of the therapy at a low cost
- how to minimize toxicity
- how to sustain the effect over a period of time

DNA therapies

ANTISENSE OLIGONUCLEOTIDES (ASOS) AND DNA APTAMERS. ASOs are single, short strands of DNA of about 8–50 bases in length. They bind to a target mRNA and either destroy it or stop it from functioning.

The use of ASOs are researched for neurodegenerative diseases, such as Alzheimer's, Parkinson's, Huntington's, and ALS. Fomivirsen and Mipomersen are the only two ASOs that have been approved by the FDA.

Fomivirsen was developed in 1998 to treat cytomegalovirus (CMV) retinitis, a serious viral eye infection. Fomivirsen is an ASO that works by binding to a section of the mRNA of the virus involved in reproducing itself. This drug effectively stops the viral infection and has a long lasting effect. It was taken off the market because very few people were getting this condition.

Mipomersen is used to treat people with familial hypercholesterolemia (FH). Their bodies cannot properly transport cholesterol out of the body, so they have high LDL levels. Left untreated, FH results in increased

cholesterol in the arteries (atherosclerosis), which in turn results in early heart attacks in young adults and sometimes in children.

Mipomersen is an ASO that binds to the mRNA of the abnormal APOB protein found in FH and prevents its synthesis. APOB is the main component of low density lipoprotein (LDL), which is responsible for carrying cholesterol to the various tissues of the body. Mipomersen helps treat FH by causing cholesterol bound to the LDL to be destroyed and cleared from the body by the liver.

The DNA aptamer is a single-stranded DNA molecule about 56–120 bases in length. Aptamers can bind to targets such as proteins, carbohydrates, molecules, and toxins, and affect their function. This can be used to treat infectious diseases and diseases that result in the production of too much or abnormal protein. Aptamers form variety of shapes that allow it to bind well to their targets.

GENE THERAPY. Gene therapy involves treating a disease by adding, removing, or changing the genetic material in the cells of a patient.

Diagram of an adenovirus (upper left) being used to administer genetic material into a cell (bottom right). Adenoviruses are DNA (deoxyribonucleic acid) viruses that infect human cells by injecting DNA into the nucleus. Usually this results in disease, but the virus can be genetically engineered so that it transplants human DNA into the cell nucleus for medically beneficial purposes. Transplanting DNA in this way can replace a faulty gene with a normal version. (Patrick Landmann/Science Source)

KEY TERMS

DNA (deoxyribonucleic acid)—The genetic material that contains the instructions for creating proteins.

DNA base—One unit in a DNA sequence. The four DNA bases are adenine (A), cytosine (C), guanine (G), and thymine (T). The sequence of these bases is the genetic code that contains the instructions for creating proteins.

DNA sequence—Contains the instructions for creating proteins. A three base sequence in the DNA contains the instructions for making a particular amino acid.

Gene—A unit of information on DNA that contains the instructions for making a protein.

Genome—The complete set of genetic instructions of an organism.

Messenger RNA (mRNA)—A sequence of bases that contain the instructions for a protein. The mRNA sequence is translated into a string of amino acids that forms a protein.

Pathogenic variant—Any change in the sequence of a genome that causes disease.

Protein—The building blocks for life that guide the development and function of the body.

Ribonucleic acid (RNA)—The genetic material that is involved in creating proteins.

Ribosome—A complex molecule made of RNA and proteins that acts like a protein synthesis factory.

Tissue—Substance that is made up of cells that have a common function. The four types of tissue are: connective, epithelial (skin), muscle, and nervous tissue.

Transfer RNA (tRNA)—A small RNA molecule that binds to a complementary mRNA sequence and then attaches the corresponding amino acid to the protein chain.

Variant—Change in the sequence of a genome.

Gene therapy was initially designed to treat inherited diseases, such as cystic fibrosis. It has been investigated as a treatment for cancers, autoimmune-diseases such as arthritis, and some infectious diseases. Gene therapy can be somatic or germline. Somatic gene therapy involves adding, removing, or changing genetic material in tissue or cells. Doing so results in the production of a naturally occurring protein that is lacking or not functioning

correctly in an individual patient. Germline gene therapy adds, removes, or changes the genetic material in reproductive cells, or early embryos in order to correct genetic defects that may be passed on to future generations.

In the United States, both nucleic acid-based (*in vivo*) treatments and cell-based (*ex vivo*) treatments are investigated. Nucleic acid-based gene therapy uses vectors (such as viruses) to deliver modified genes to target cells. Cell-based gene therapy techniques remove cells from the patient in order to genetically alter them then reintroduce them to the patient's body. As of 2021, gene therapies for the following diseases were being developed in the United States: cystic fibrosis (using adenoviral vector); HIV infection (cell-based); malignant melanoma (cell-based); Duchenne muscular dystrophy (cell-based); hemophilia B (cell-based); kidney cancer (cell-based); Gaucher disease (retroviral vector); breast cancer (retroviral vector); and lung cancer (retroviral vector). When a cell or individual is treated using gene therapy and successful incorporation of engineered genes has occurred, the cell or individual is said to be transgenic.

RNA therapies

In the early 1980s, researchers discovered that RNA plays a major role in all areas of protein synthesis. These findings laid the groundwork for RNA therapies.

RNA INTERFERENCE AND SHORT INTERFERING RNAS (SIRNAS). In 1986, RNA interference was discovered (RNAi). RNAi is naturally used by an organism to provide protection from invading viruses by preventing the translation of certain genes into proteins. Researchers call this gene silencing.

RNA interference therapy is done with short interfering RNAs (siRNAs), which are small fragments of RNA about 21 bases long. During RNAi, a siRNA binds to a complementary sequence of mRNA in a cell, which results in the destruction or inactivation of the mRNA and prevents the translation of mRNA into protein.

RNAi is used by researchers to study gene function. RNAi is also studied to treat infectious diseases and genetic conditions that result in the production of abnormal proteins, such as many cancers and neurodegenerative diseases. It can be used against cancer by blocking the production of proteins in cancer cells so that they die or stop multiplying. siRNAs are more stable than ASOs, which is an advantage. Potential problems with siRNA include their being challenging to deliver to the cell and their mistakenly suppressing other (unintended) genes.

Three siRNA therapies have been approved in the United States. Patisiran, approved in 2018, is used to treat hereditary transthyretin amyloidosis (hATTR), a progressive condition that results from increased transthyretin protein

and damage to various organs, including the nerves. Build up of transthyretin in the nerves causes loss of function of the lower limbs, feet, and hands. hATTR can also affect the heart, kidneys, eyes, and gastrointestinal tract. Patisiran reduces the production of transthyretin, which in turn reduces the symptoms and slows progression of the disease.

MICRORNAS (MIRNAS). MicroRNAs (miRNAs) are short RNA molecules that do not have instructions for the creation of a protein. miRNAs help to balance proteins in the body by reducing the production of a protein when there is too much already in the body. Dysregulation of miRNAs is a common cause of symptoms in many diseases. One benefit of using miRNAs is that they can target multiple genes at once. This ability can be useful for the treatment of diseases such as cancer, which results from the dysregulation of multiple proteins.

miRNAs therapies are being developed for Huntington's disease, which is caused by a pathogenic variation (mutation) in the huntingtin (HTT) gene, which results in the production of an abnormal HTT protein. This causes progressive deterioration, uncontrolled movements, mental health problems, and cognitive decline. The abnormal HTT protein appears to decrease the function of naturally occurring miRNAs, which causes the overproduction of the proteins these miRNAs normally regulate. The overproduction of proteins causes the symptoms of Huntington's disease. The RNAi therapies that are being developed for Huntington's disease deliver miRNAs that destroy the mRNA for HTT. This results in a decrease in production of the HTT protein. These therapies have as of 2021 only been tested in animals, but they appear to decrease the level of HTT while improving motor function and increasing lifespan.

RNA APTAMERS (RNA DECOYS). RNA aptamers are small RNAs that can bind to proteins and prevent their functioning. They can also be used to transport siRNAs into the cell. An advantage of RNA aptamers is that they can target compounds both outside and inside the cell. Unlike other RNA therapies, they do not need to enter the cell in order to work.

Pegaptanib was the first RNA aptamer approved in the United States. Pegaptanib treats age-related macular degeneration (AMD), which causes severe and progressive vision problems. Pegaptanib binds to a protein called VEGF, which inhibits the production of new blood vessels that can become out of control in AMD.

RIBOZYMES. Ribozymes are a type of RNA that can be used to suppress gene function. They work by binding to an mRNA and preventing the production of a protein. Both naturally occurring and synthesized ribozymes can be used in therapy. Two promising areas for ribozyme therapies are cancer and virology. Ribozymes can also be used in drug development to identify genes that have a particular function and would be good targets for new therapies.

QUESTIONS TO ASK YOUR DOCTOR

- Would any nucleic acid therapies help treat my disease?
- What are the risks of nucleic acid therapies?
- Are there any clinical trials for nucleic acid therapies that I might join?

CIRCULAR RNAS. Circular RNAs have the ends of their strand stuck together, unlike typical RNA, which forms a linear strand. Circular RNAs do not usually contain the instructions for the production of proteins. Circular RNAs seem to be a risk factor for a number of diseases, such as atherosclerosis, Parkinson's disease, Alzheimer's disease, and cancers. Researchers study the role of circular RNAs and ways in which they might be used as therapies.

Obesity

Definition

Obesity is the state of being overweight to the degree that one's health and potential life expectancy are affected. Clinically, obesity is measured by using a scale called body mass index (BMI), which is calculated by dividing weight in kilograms by the square of height in meters. According to the Centers for Disease Control and Prevention (CDC), Division of Nutrition, Physical Activity, and Obesity, a BMI of 30.0 or higher is considered clinically obese.

Description

Obesity is caused when a person consumes more calories than is needed to fuel his or her body. According to the CDC, about 40% of all American adults and 20% of American adolescents are overweight. This is a serious public health concern, since overweight and obesity are associated with serious illnesses that are among the leading causes of death worldwide, such as heart disease, diabetes, stroke, and cancer.

Genetic profile

Many genetic syndromes include obesity as a feature. In these syndromes, genetic mutations have been identified that cause obesity. Syndromes associated with obesity include Alstrom syndrome, Bardet-Biedl syndrome, Cohen syndrome, fragile X syndrome, Leptin receptor deficiency, and Prader-Willi syndrome. In many of these syndromes, an identified genetic mutation causes an abnormal protein to be formed. The abnormal protein alters perception and senses so that the individual constantly feels hungry and is unable to feel full or satiated after eating, which leads to an obsession with food and to overeating and obesity. Overeating is a hallmark feature of Prader-Willi syndrome in particular. Mutations in the following genes have been shown to cause obesity

within syndromes: *ALMS1*, *BBS1*, *BBS10*, *FMRI*, *LEP*, *LEPR*, *OCA2*, and *VSB13B*.

Using BMI as a measure for obesity, researchers have determined that it is a heterogeneous trait impacted by multiple genetic and environmental factors. Estimates of the heritability of BMI vary from 31% to 90%. Monogenetic obesity is caused by mutations of a single gene, and such mutations generally result in severe, early-onset obesity. Genetic mutations in the melanocortin system, which control energy balance, such as leptin (*LEP*), leptin receptor (*LEP*), proopiomelanocortin

Visualization of the location of the "obesity gene" (FTO) in region 16q12.2 (highlighted) on chromosome 16. The FTO gene is widely expressed or "turned on" in the hypothalamus (the part of the brain that controls appetite) and in the pancreatic islets where insulin is produced. People who have one copy of FTO weigh, on average, 4.5 lbs more than people who do not have it; people who have two copies weigh about 9 lbs more on average. (The Visual MD/ Science Source)

(*POM*), melanocortin-4 receptor (*MC4R*), preproconvertase 1 (*PCSK1*), single-minded 1 (*SIM1*), brain-derived neurotrophic factor (*BDNF*), and tyrosine kinase receptor tropomyosin-related kinase B (*TrkB*), are associated with monogenic obesity.

Genome-wide association studies (GWAS) have identified more than 900 genetic variants associated with risk for, and development of, polygenic obesity. *FTO* on chromosome 16 is one of the most studied genes associated with fat mass and obesity. Variants of this gene are associated with either high or low risk of obesity. Among the many other genes associated with BMI and obesity are: *BMIQ1* (7q31), *BMIQ2* (13q14), *BMIQ3* (6q23-q25), *BMIQ4* aka:*UCP2* (11q24), *BMIQ5* (16p13), *BMIQ6* (20pter-p11.2), *BMIQ7* (4p15-p14), *BMIQ8* (10p), *BMIQ9* (*MC3R*) (20q), *BMIQ10* (*FFAR4*) on ch10q, *BMIQ11* aka:*SLC6A14* (Xq24), *BMIQ12* aka:*PCSK1* (5q15-q21), *BMIQ13* (2q14.1), *BMIQ14* (16q12.2), *BMIQ15* (17q23.2-q25.1), *BMIQ16* (16p11.2), *BMIQ17* (9p13.3), and *BMIQ18*(6q14.2). These genes contribute to obesity through a variety of different mechanisms. Mutations in the *BMIQ10* gene change proteins that metabolize fatty acids, which leads to abnormal insulin response. Mutations in the *BMIQ9* gene alter energy homeostasis and energy use so that, even when less food is consumed, weight still remains high. Mutations in the *BMIQ12* gene alter hormones that are thought to contribute to reduced metabolic rate and disrupted absorption in the small intestine. Mutations in *BMIQ11* are thought to be associated with X-linked obesity. When examining this gene, a significant difference was found between obese and non-obese individuals. Mutations in the *BMIQ4* gene lead to a weakening of the mitochondrial membrane, causing them to leak ATP and to be inefficient delivery vessels for energy in the body. Many of these mutations are also associated with higher rates of diabetes.

GWAS also found that several genes involved in governing energy homeostasis (the balance of energy intake and expenditure) including *LEP*, *POMC*, *BDNF*, *PCSK1*, *SIM1*, and *TrkB* are associated with obesity as well as with development of the central nervous system and neurodegenerative diseases. Other genes associated with obesity including *NEGR1*, *NRXN3*, *CADM2*, *GRID1*, *ELAVL4*, and *SCG3* are related to synaptic function and neurotransmitter signaling, the processes used by neurons to communicate with other cells.

As research into the genetics of obesity continues, more genes related to the complex functions of metabolism and body size are discovered, and the intricate interplays among obesity, genetics, and environment are explored. For example, research reveals that environmental factors such as lifestyle changes (exercise and diet)

A doctor examining an obese patient. (Sunabesyou/Shutterstock)

can modulate the obesity risk associated with some genetic variants.

In 2021, researchers reported identification of 62 genes that are associated with higher levels of body fat and a lower risk of cardiovascular and metabolic diseases. The genes are involved with a variety of functions, including regulation and development of fat cells, distribution of body fat, energy regulation, and inflammation. These genes may help to explain why up to 45% of people who are obese have healthy blood pressure, glucose, and lipid levels and as a result are not at increased risk for many conditions caused or exacerbated by obesity.

Another study published in 2021 finds that the genetic risk factors associated with childhood obesity differ from those in adulthood. The researchers developed polygenic risk scores (scores that indicate the risk of developing a disease or disorder when compared to people who have a different genetic constitution) for people of various ages. They found that childhood scores accurately predicted BMI at age 10 and that adult risk scores predicted adult BMI. The researchers also suggest that the genetic risks for childhood obesity vary by race and ethnicity. These findings may be used to develop obesity-prevention programs.

Many discoveries about genetic factors that contribute to non-syndromic obesity have come from the Human Microbiome Project. The term “microbiome” refers to all of the genetic material contained in the micro-organisms in and on the human body. Much of this research has focused on the micro-organisms of the human digestive tract, or gut. Researchers have discovered a symbiotic relationship between the bacteria in the gut and the health of the human host. Most of the bacteria found in the human body are beneficial and necessary for health. Researchers have found that there is a significant difference between the metabolic activities of the micro-

KEY TERMS

Calorie—A unit of energy that represents the amount of heat a specific amount of food will create in the human body.

Energy homeostasis—The ability of all living things to maintain energy balance.

Heterogeneous trait—A trait that is caused by both genetic and nongenetic factors.

Hypertension—High blood pressure.

Prader-Willi syndrome—A rare genetic disorder caused by missing genes on chromosome 15. Individuals with this syndrome have intellectual and physical symptoms and a constant feeling of hunger that may cause them to overeat.

organisms in the digestive tract of lean individuals and those of obese individuals, suggesting that the genetics of the microbiome is a contributing factor in obesity.

Demographics

In 2019, the most recent year for which data were available, more than 42% of all American adults were obese, up 26% from 2008. Among youth, obesity rates were similar for males and females. Among adults, females had a higher obesity rate than males, and middle-aged males and females had a higher rates of obesity than younger males and females. African Americans had higher obesity rates (49.6%) than Latinx (44.8%) or white Americans (42.2%), and the lowest obesity rates in adults were seen in adults of Asian descent (17.4%).

Signs and symptoms

The definition of obesity is a BMI of 30.0 or greater.

Diagnosis

Obesity is diagnosed by physical examination. Genetic screenings may be helpful in determining whether obesity is caused by genetic mutations or environmental factors or, most likely, a combination of both. This information may be useful in developing treatment plans and strategies.

Treatment and management

Treatment for obesity that is not part of a genetic syndrome generally involves diet management and exercise. Registered dietitians and physical therapists may

be helpful in ensuring that the individual is able to approach weight loss in a healthy way. A supportive peer group and counseling to address the psychological issues surrounding eating have also been shown to be helpful additions to a treatment plan.

Medication may be prescribed to help reduce appetite. The medical guidelines for the use of medications to aid weight loss include a BMI of 30 or greater, or a BMI of 27 or greater in the presence of medical complications such as diabetes, hypertension, or sleep apnea. Common weight-loss medications include orlistat (Xenical), lorcaserin (Belviq), phentermine and topiramate (Qsymia), bupropion and naltrexone (Contrave), and liraglutide (Saxenda). Medication might not be suitable for individuals with certain medical conditions such as cardiac disease, people taking some other medications, or pregnant women.

In cases of clinically severe obesity, which may be life-threatening (people with a BMI of 40 or higher, or those with a BMI of 35 to 39.9 and other medical conditions), surgical treatment such as gastric bypass surgery, LapBand, or gastric sleeve may be prescribed.

Gastric bypass involves restricting the size of the stomach by stapling the stomach to itself and creating a smaller upper portion to receive food, and a larger lower portion that is not used. The next step connects the smaller upper pouch of the stomach directly to the small intestine so that the food travels from the pouch directly to the small intestine, and less food is absorbed. Weight loss occurs because far fewer calories may be consumed. The risks associated with gastric bypass include less than one percent mortality in the 30 days following surgery; however, the vast majority of patients who have gastric bypass have fewer comorbidities, a longer life expectancy, and lower risk of death.

Another surgical treatment is laparoscopic adjustable gastric banding (LAGB), also called LapBand. Much like gastric bypass, the stomach is separated into two sections; however, rather than using staples, the stomach is divided using an inflatable band. Like a belt, the band is pulled tight, thus creating a small channel between the two pouches. The band keeps the opening from expanding and may be left in place permanently.

A more invasive and major surgery, biliopancreatic diversion with duodenal switch, involves removing a large part of the stomach. The surgeon leaves the valve that releases food to the small intestine and the first part of the small intestine (duodenum). Next, the middle section of the intestine is closed, and the last part is attached to the duodenum. The separated section of the intestine is reattached to the end of the intestine to allow

QUESTIONS TO ASK YOUR DOCTOR

- How can I manage my child's constant need to eat?
- How can I help my child lose weight?
- What is my BMI?
- Which treatment would you recommend?
- Should I consider surgery or medications?
- What other conditions do I have?
- What other diseases am I at risk of developing?

bile and digestive juices to flow into this part of the intestine.

Another surgical treatment for obesity is gastric sleeve. In this procedure, part of the stomach is removed, creating a smaller pouch. Less complicated than gastric bypass or biliopancreatic diversion with duodenal switch, this procedure does not involve reconnecting to the duodenum.

In 2014, the FDA approved a treatment for obesity called vagal nerve blockade. It involves implanting a device under the skin of the abdomen. The device sends electrical pulses to the abdominal vagus nerve, which tells the brain when the stomach feels empty or full. The FDA approved vagal nerve blockage for use by adults with a BMI of 35 to 39.9 who have been unable to lose weight with a weight-loss program and who have at least one obesity-related condition, such as type 2 diabetes.

In 2015, the FDA approved a dual-balloon system for obesity treatment of patients with a BMI of 30 to 40 and one or more obesity-related condition. In this treatment, two attached balloons are inserted into the patient's stomach and then filled with saltwater. The balloons take up space in the patient's stomach for up to six months, after which time they should be removed.

Following weight loss, it is important to have a plan to help prevent regaining the weight. The most effective way to avoid regaining weight is through exercise and physical movement. Doctors recommend attempting 40 to 60 minutes of exercise per day. It may be helpful to maintain a support group and continue counseling after a goal weight has been reached.

Treatment for obesity for individuals with genetic syndromes involves a more psychological, behavioral approach. It is important to consider the developmental level of the individual when planning interventions, since many individuals with genetic syndromes also have

developmental delays or intellectual disabilities. Limiting access to food (except during meals) is important, as is following a nutritious meal plan. A registered dietician with experience working with individuals with special genetic conditions is a great addition to the health care team.

Prognosis

Individuals with obesity are at risk of developing serious and sometimes life-threatening medical conditions such as diabetes, heart disease, hypertension, sleep apnea, and stroke, and they are at increased risk of developing several types of cancer, including cancers of the colon, esophagus, gallbladder, kidney, pancreas, liver, and prostate, as well as uterine and postmenopausal breast cancer. The CDC estimates that there are over 300,000 premature deaths in the United States each year due to obesity. Left untreated, the prognosis may be poor; however, with proper nutrition and weight loss, many of the risks can be reduced or eliminated.

Obesity-hypotonia syndrome see **Cohen syndrome**

Oculodentodigital syndrome

Definition

Oculodentodigital syndrome (ODDS) is a relatively rare genetic condition with specific medical findings involving the eyes, skeletal system, brain, dentition, and face.

Description

Most fully described by the German ophthalmologist Dr. Gerard Meyer-Schwickerath and others in 1957, today ODDS is also known as oculodentodigital dysplasia, oculodentosseous dysplasia, and Meyer-Schwickerath syndrome.

People with ODDS experience symptoms differently. Overall, the symptoms usually affect the eyes, teeth, hands, feet, face, bones, hair, and brain.

Common signs of ODDS include a slightly indented nasal bone, thin nose with small nasal openings, thin and upturned nostrils, small eyes with iris abnormalities, small corneas, webbing of the fingers or toes, and weakened enamel on the teeth.

Genetic profile

ODDS is an inherited disorder caused by mutations in *GJA1*, also known as the connexin-43 gene. This gene is located on chromosome 6.

ODDS is most commonly inherited in an autosomal dominant pattern. In this type, family history of the

syndrome is common and the condition may be present in several generations. A person with ODDS has a 50% of having an affected child. The exact signs and symptoms may vary from person to person, even within the same family.

Instances of autosomal dominant inheritance with no family history also exist, in which a person develops ODDS from a new mutation that occurred by chance during his or her conception. There are reports of these chance mutations being possibly associated with an older average age for the father.

Rarely, ODDS has been reported to follow an autosomal recessive pattern of inheritance. In this type, there may be no family history and the condition may only show up in one generation. Two parents would have a 25% chance of having another affected son or daughter once their child is diagnosed with ODDS.

In 1997, a unique family history of ODDS was reported. In this family, relatives in successive generations had more severe neurological signs of ODDS than their older relatives, and these signs showed up at an earlier age in each successive generation. A similar family history was reported in 2002, again involving neurological symptoms of ODDS. These patterns suggest the genetic phenomenon called anticipation, which has been described in other genetic conditions. The hallmark of anticipation is people with progressively worse symptoms in successive generations of the same family.

Demographics

ODDS occurs worldwide, affecting males and females equally. The exact incidence is not known, but it is not a common condition.

Signs and symptoms

Ocular and facial findings

Small, sunken eyes that are closer together or wider apart are common features in ODDS. Additionally, the corneas of a person with ODDS may be smaller than normal. Other eye findings include glaucoma, cataracts, iris abnormalities, poor vision, and an extra fold of skin near the nose at the upper eyelid.

Facial characteristics of people with ODDS can be unique to them and their affected family members. A striking facial feature is the narrow, longer nose seen in the condition. People with ODDS may also have narrow and upturned nostrils, a prominent jaw, and smaller head size.

Dental and mouth findings

A common dental finding of ODDS is weaker tooth enamel, making teeth prone to decay and cavities. People with ODDS may also be born with teeth that are smaller than average, missing teeth, or have a premature loss of teeth. Cleft lip and cleft palate have also been seen in ODDS.

Skeletal and digital findings

People with ODDS can have enlargement of specific bones. These include bones in the hands, feet, ribs, and skull. This can cause the forearm to turn outward in some people. Some with the condition are prone to their hips dislocating.

The hands and feet of people with ODDS can be significantly affected. Some may have severe webbing between their fourth and pinky fingers, so much so that they look like one large, joined finger. The pinky finger may be shortened, curved, or permanently flexed as well. Webbing has also been seen between the third and fourth toes of people with ODDS.

Neurological findings

Less emphasis has been given to the neurological and other associated symptoms of ODDS, though they can be very problematic for the person with the syndrome. Some people with ODDS have very tight and stiff muscles with increased reflexes. This can result in difficulty with controlled muscle movements such as those needed for walking and speaking. Intellectual disabilities are sometimes seen, and others may have muscle weakness of their limbs that can be similar to paralysis.

Changes in the brain are found in people with ODDS. Examples of these are loss in the natural white matter and hardening within some brain structures.

Other findings

A common finding in ODDS is conductive hearing loss, which is usually related to sound waves not being able to travel through the normal ear pathways.

Thickening of the skin on the palms and soles of people with ODDS is common. It may be yellow-orange in color, but is not usually associated with blisters.

Another occasional finding in ODDS is very fine, dry hair. It may also be sparse and slower to grow than usual.

Diagnosis

Genetic testing from a blood sample is available for those suspected to have a clinical diagnosis. This testing

studies the *GJA1* gene carefully to look for disease-causing mutations. An abnormal genetic test result is one that finds a mutation in a person's copy of *GJA1*. Finding this mutation confirms the diagnosis of ODDS. Once a mutation has been found, other at-risk family members can also be tested. Genetic testing can also be offered during the second trimester of a pregnancy via an amniocentesis procedure, if a couple desires such information during that time.

Genetic testing should be offered in conjunction with careful genetic counseling for the affected individual, the family members, or the expectant couple.

A diagnosis is more often made after the careful identification and study of a person's symptoms and family history. A diagnosis may be suspected by a team of specialists, including an ophthalmologist, dermatologist, dentist, orthopedist, medical geneticist, neurologist, and otolaryngologist.

Treatment and management

Ocular and facial findings

The formation or appearance of the eyes cannot be treated and typically does not cause medical complications. Glaucoma, however, can lead to vision loss or blindness if left untreated. It may be treated with prescription eye drops, surgery, or laser treatments. The goal of glaucoma treatments is to reduce the pressure within the eye, thereby reducing the risk of damage to the eye structures and subsequent vision loss.

Some cataracts may be treated with surgery to remove the natural lens of the eye using various procedure options. The ophthalmologist will then replace it with a new, clear artificial lens. Some cataracts, especially those present at birth, may not be treatable and also may not cause serious vision problems for the person.

Facial characteristics seen in ODDS are not treatable and usually cause no medical complications.

Dental and mouth findings

People with ODDS have teeth that are prone to decay and cavities. Dentists can treat these to prevent further decay; teeth left untreated may need to be removed if the decay is too severe. Common treatment for cavities can include fillings, crowns, or root canal procedures in more complicated cases.

Those with a cleft lip may have it corrected with a surgery in the first few months of life. A cleft palate can be repaired through stages of surgery, often first happening in the first year of life. These surgeries usually require a multidisciplinary team consisting of a plastic surgeon,

KEY TERMS

Amniocentesis—A procedure involving removal of a small amniotic fluid sample during pregnancy to obtain fetal chromosome results.

Cataract—A change in the eye's lens that causes it to become cloudy in appearance, rather than clear.

Cleft lip—Abnormal opening in the upper lip.

Cleft palate—Abnormal opening in the upper roof of the mouth.

Cornea—Transparent outer layer of the eyeball.

Glaucoma—An eye disease that usually involves high pressure in the eye, which can lead to vision problems or blindness if left untreated.

Iris—Colored part of the eye that contains the pupil in the center.

Magnetic resonance imaging (MRI) scan—Procedure that shows internal organs and tissues of the body using magnetic fields and signals.

Mutation—Small change in the sequence of a gene.

pediatric dentist, pediatric anesthesiologist, nurses, dietitian/feeding specialist, and social worker.

Skeletal and digital findings

Many of the internal bone changes in people with ODDS cannot be treated. Those with significant webbing between their fingers and toes may find surgery helpful to gain mobility, the use of their digits, or cosmetic improvement. In cases where the bones are not webbed, surgery to separate the fingers or toes may be possible with the help of an orthopedic surgeon and plastic surgeon.

Children with hips that dislocate may require treatment with a harness or splint that keeps the hips in place. If this is not successful, a plaster cast may be necessary. Sometimes surgery by an orthopedic surgeon is needed to replace a hip in more severe cases.

Neurological findings

A magnetic resonance imaging (MRI) scan or other imaging study of the brain can document the changes sometimes seen in ODDS. Treatments may help those with increased muscle tone and problems with stiffness. Medications, physical therapy involving motion exercises, active stretching exercises, and occupational therapy can help. A combination of these is important in order for the person with ODDS to gain mobility and independence.

Mental delays and intellectual disabilities may be assessed by a child development team or early childhood program. Extra assistance is sometimes available through early intervention programs and special education in schools. Social workers are useful to connect families to helpful resources.

Other findings

Hearing loss is best assessed and treated by an otolaryngologist and audiologist. Once determined as conductive hearing loss, treatments can include the use of antibiotics if an infection is present, ear drops, or hearing aids.

Skin changes are best assessed and treated by a dermatologist. Treatments may include the use of topical ointments or creams. Oral medications or carefully removing the outermost layer of skin to reduce thickness is helpful in some people. Treatments to change the hair texture or thickness are not usually necessary because it causes no medical complications.

A psychologist, genetic counselor, or therapist can be helpful for some people with ODDS. Living with visible skin and digit changes can be difficult, and some may find it easier to talk to an objective person or to other families in a support group.

Prognosis

ODDS can involve a combination of severe medical complications in some cases. Since no two people experience the exact same type of symptoms, it is impossible to predict which characteristics a child newly diagnosed with the condition will exhibit. No specific lifespan ranges are known, but might be lower in those who have more serious medical concerns. Newer medical treatments continue to offer hope for those with ODDS and their families.

Oligohydramnios sequence

Definition

Oligohydramnios sequence occurs as a result of having very little or no fluid (called amniotic fluid) surrounding a developing fetus during a pregnancy. “Oligohydramnios” means that there is less amniotic fluid present around the fetus than normal. A “sequence” is a chain of events that occurs as a result of a single abnormality or problem. Oligohydramnios sequence is therefore used to describe the features that a fetus develops as a result of very low or absent amount of amniotic fluid. In 1946, Dr. Edith Potter first described the physical features seen in oligohydramnios sequence. Because of her description, oligohydramnios sequence has also been known as Potter syndrome or Potter sequence.

Description

During a pregnancy, the amount of amniotic fluid typically increases through the seventh month and then slightly decreases during the eighth and ninth months. During the first 16 weeks of the pregnancy, the mother’s body produces the amniotic fluid. At approximately 16 weeks, the fetal kidneys begin to function, producing the majority of the amniotic fluid from that point until the end of the pregnancy. The amount of amniotic fluid, as it increases, causes the space around the fetus

(amniotic cavity) to expand, allowing enough room for the fetus to grow and develop normally.

Oligohydramnios typically is diagnosed during the second and/or third trimester of a pregnancy. When the oligohydramnios is severe enough and is present for an extended period of time, oligohydramnios sequence tends to develop. There are several problems that can cause oligohydramnios to occur. Severe oligohydramnios can develop when there are abnormalities with the fetal renal system or when there is a constant leakage of amniotic fluid. Sometimes, the cause of the severe oligohydramnios is unknown.

Approximately 50% of the time, fetal renal system abnormalities cause severe oligohydramnios, resulting in the fetus developing oligohydramnios sequence. This is because if there is a problem with the fetal renal system, there is the possibility that not enough amniotic fluid is being produced. Renal system abnormalities that have been associated with the development of oligohydramnios sequence include the absence of both kidneys (renal

Low-set ears are a common feature of infants with oligohydramnios sequence. (Custom Medical Stock)

agenesis), bilateral cystic kidneys, absence of one kidney with the other kidney being cystic, and obstructions that block the urine from exiting the renal system. In a fetus affected with oligohydramnios sequence, sometimes the renal system abnormality is the only abnormality the fetus has. However, approximately 54% of fetuses with oligohydramnios sequence due to a renal system abnormality will have other birth defects or differences with their growth and development. Sometimes the presence of other abnormalities indicates that the fetus may be affected with a syndrome or condition in which a renal system problem can be a feature. Renal system abnormalities in a fetus can also be associated with certain maternal illnesses, such as insulin-dependent diabetes mellitus, or the use of certain medications during a pregnancy.

Severe oligohydramnios can also develop even when the fetal renal system appears normal. In this situation, often the oligohydramnios occurs as the result of chronic leakage of amniotic fluid. Chronic leakage of amniotic fluid can result from an infection or prolonged premature rupture of the membranes that surround the fetus (PROM). In chronic leakage of amniotic fluid, the fetus still produces enough amniotic fluid; however, there is an opening in the membrane surrounding the fetus, causing the amniotic fluid to leak out from the amniotic cavity.

Genetic profile

The chance for oligohydramnios sequence to occur again in a future pregnancy or in a family member's pregnancy is dependent on the underlying problem or syndrome that caused the oligohydramnios sequence to develop. There have been many fetuses affected with oligohydramnios sequence where the underlying cause of the severe oligohydramnios has been a genetic abnormality. However, not all causes of severe oligohydramnios that result in the development of oligohydramnios sequence have a genetic basis. The genetic abnormalities that have caused oligohydramnios developing during a pregnancy include a single gene change, a missing gene, or a chromosome anomaly.

Although some fetuses with oligohydramnios sequence have been found to have a chromosome anomaly, the likelihood that a chromosome anomaly is the underlying cause of the renal system anomaly or other problem resulting in the severe oligohydramnios is low. A chromosome anomaly can be a difference in the total number of chromosomes a fetus has (such as having an extra or missing chromosome), a missing piece of a chromosome, an extra piece of a chromosome, or a rearrangement of the chromosomal material. Some of the chromosome anomalies can occur for the first time at the conception of the fetus (sporadic), while other chromosome anomalies can be inherited from a parent. Both

sporadic and inherited chromosome anomalies have been seen in fetuses with oligohydramnios sequence. The chance for a chromosome anomaly to occur again in a family is dependent on the specific chromosome anomaly. When the chromosome anomaly is considered to be sporadic, the chance for chromosome anomaly to occur again in a pregnancy is 1% added to the mother's age-related risk to have a baby with a chromosome anomaly. If the chromosome anomaly (typically a rearrangement of chromosomal material) was inherited from a parent, the recurrence risk would be based on the specific chromosome arrangement involved. However, even if a chromosome anomaly were to recur in a future pregnancy, it does not necessarily mean that the fetus would develop oligohydramnios that could cause the development of oligohydramnios sequence.

Many of the genetic conditions that can cause oligohydramnios sequence are inherited in an autosomal recessive manner. An autosomal recessive condition is caused by a difference in a gene. Like chromosomes, the genes also come in pairs. An autosomal recessive condition occurs when both genes in a pair don't function properly. Typically, genes don't function properly because there is a change within the gene causing it not to work or because the gene is missing. An individual has an autosomal recessive condition when they inherit one non-working gene from their mother and the same non-working gene from their father. These parents are called "carriers" for that condition. Carriers of a condition typically do not exhibit any symptoms of that condition. With autosomal recessive inheritance, when two carriers for the same condition have a baby, there is a 25% chance for that baby to inherit the condition. There are several autosomal recessive conditions that can cause fetal renal abnormalities potentially resulting in the fetus developing oligohydramnios sequence.

Oligohydramnios sequence has also been seen in some fetuses with an autosomal dominant condition. An autosomal dominant condition occurs when only one gene in a pair does not function properly or is missing. This non-working gene can either be inherited from a parent or occur for the first time at conception. There are many autosomal dominant conditions where affected family members have different features and severity of the same condition. If a fetus is felt to have had oligohydramnios sequence that has been associated with an autosomal dominant condition, it would have to be determined if the condition was inherited from a parent or occurred for the first time. If the condition was inherited from a parent, that parent would have a 50% chance of passing the condition on with each future pregnancy.

Sometimes the fetus with oligohydramnios sequence has a condition or syndrome that is known to occur

KEY TERMS

Anomaly—Different from the normal or expected. Unusual or irregular structure.

Bilateral—Relating to or affecting both sides of the body or both of a pair of organs.

Fetus—The term used to describe a developing human infant from approximately the third month of pregnancy until delivery. The term “embryo” is used prior to the third month.

Hypoplasia—Incomplete or underdevelopment of a tissue or organ.

Renal system—The organs involved with the production and output of urine.

Syndrome—A group of signs and symptoms that collectively characterize a disease or disorder.

Teratogen—Any drug, chemical, maternal disease, or exposure that can cause physical or functional defects in an exposed embryo or fetus.

Unilateral—Refers to one side of the body or only one organ in a pair.

sporadically. Sporadic conditions are conditions that tend to occur once in a family and the pattern of inheritance is unknown. Since there are some families where a sporadic condition has occurred more than one time, a recurrence risk of approximately 1% or less is often given to families where only one pregnancy has been affected with a sporadic condition.

Sometimes examinations of family members of an affected pregnancy can help determine the exact diagnosis and pattern of inheritance. It is estimated that approximately 9% of first-degree relatives (parent, brother, or sister) of a fetus who developed oligohydramnios sequence as a result of a renal abnormality will also have renal abnormalities that do not cause any problems or symptoms. It is important to remember that if a pregnancy inherits a condition that is associated with oligohydramnios sequence, it does not necessarily mean that the pregnancy will develop oligohydramnios sequence. Therefore, for each subsequent pregnancy, the risk is related to inheriting the condition or syndrome, not necessarily to developing oligohydramnios sequence.

Demographics

There is no one group of individuals or one particular sex that has a higher risk to develop oligohydramnios sequence. Although, some of the inherited conditions that have been associated with oligohydramnios sequence

may be more common in certain regions of the world or in certain ethnic groups.

Signs and symptoms

With severe oligohydramnios, because of the lack of amniotic fluid, the amniotic cavity remains small, thereby constricting the fetus. As the fetus grows, the amniotic cavity tightens around the fetus, inhibiting normal growth and development. This typically results in the formation of certain facial features, overall small size, wrinkled skin, and immobile arms and legs.

The facial features seen in oligohydramnios sequence include a flattened face; wide-set eyes; a flattened, beaked nose; ears set lower on the head than expected (low-set ears); and a small, receding chin (micrognathia).

Because the movement of the arms and legs are restricted, a variety of limb deformities can occur, including bilateral clubfoot (both feet turned to the side), dislocated hips, broad flat hands, and joint contractures (inability for the joints to fully extend). Contractures tend to be seen more often in fetuses where the oligohydramnios occurred during the second trimester. Broad, flat hands tend to be seen more often in fetuses where the oligohydramnios began during the third trimester.

Fetuses with oligohydramnios sequence also tend to have pulmonary hypoplasia (underdevelopment of the lungs). The pulmonary hypoplasia is felt to occur as a result of the compression of the fetal chest (thorax), although it has been suggested that pulmonary hypoplasia may develop before 16 weeks of pregnancy in some cases. Therefore, regardless of the cause of the severe oligohydramnios, the physical features that develop and are seen in oligohydramnios sequence tend to be the same.

Diagnosis

An ultrasound examination during the second and/or third trimester of a pregnancy is a good tool to help detect the presence of oligohydramnios. Since oligohydramnios can occur later in a pregnancy, an ultrasound examination performed during the second trimester may not detect the presence of oligohydramnios. In pregnancies affected with oligohydramnios, an ultrasound examination can be difficult to perform because there is less amniotic fluid around the fetus. Therefore, an ultrasound examination may not be able to detect the underlying cause of the oligohydramnios.

In some situations, an amniocentesis (injection of fluid into the amniotic cavity) is performed. This can sometimes help determine if the cause of the oligohydramnios was leakage of the amniotic fluid.

Amnioinfusions may also be used to help visualize the fetus on ultrasound in attempts to detect any fetal abnormalities.

Additionally, maternal serum screening may detect the presence of oligohydramnios in a pregnancy. Maternal serum screening is a blood test offered to pregnant women to help determine the chance that their baby may have Down syndrome, Trisomy 18, and spina bifida. This test is typically performed between the 15th and 20th week of a pregnancy. The test works by measuring amount of certain substances in the maternal circulation.

Alpha-fetoprotein (AFP) is a protein produced mainly by the fetal liver and is one of the substances measured in the mother's blood. The level of AFP in the mother's blood has been used to help find pregnancies at higher risk to have spina bifida. An elevated AFP in the mother's blood, which is greater than 2.5 multiples of the median (MoM), has also been associated with several conditions, including the presence of oligohydramnios in a pregnancy. Since oligohydramnios is just one of several explanations for an elevated AFP level, an ultrasound examination is recommended when there is an elevated AFP level. However, not all pregnancies affected with oligohydramnios will have an elevated AFP level; some pregnancies with oligohydramnios will have the AFP level within the normal range.

Because fetuses with oligohydramnios sequence can have other anomalies, a detailed examination of the fetus should be performed. Knowing all the abnormalities a fetus has is important in making an accurate diagnosis. Knowing the cause of the oligohydramnios and if it is related to a syndrome or genetic condition is essential in predicting the chance for the condition to occur again in a future pregnancy. Sometimes the fetal abnormalities can be detected on a prenatal ultrasound examination or on an external examination of the fetus after delivery. However, several studies have shown that an external examination of the fetus can miss some fetal abnormalities and have stressed the importance of performing an autopsy to make an accurate diagnosis.

Treatment and management

There is currently no treatment or prevention for oligohydramnios sequence. Amnioinfusions, which can assist in determining the cause of the oligohydramnios in a pregnancy, are not recommended as a treatment for oligohydramnios sequence.

Prognosis

Pregnancies affected with oligohydramnios sequence can miscarry, be stillborn, or die shortly after birth. This

condition is almost always fatal because the lungs do not develop completely (pulmonary hypoplasia).

Omphalocele

Definition

An omphalocele occurs when the abdominal wall does not close properly during fetal development. The extent to which abdominal contents protrude through the base of the umbilical cord will vary. A membrane usually covers the defect.

Description

An omphalocele is an abnormal closure of the abdominal wall. Between the sixth and tenth weeks of pregnancy, the intestines normally protrude into the umbilical cord as the baby is developing. During the tenth week, the intestines should return and rotate in such a way that the abdomen is closed around the umbilical

KEY TERMS

Acetylcholinesterase (ACHE)—An enzyme found in nerve tissue.

Alpha-fetoprotein (AFP)—A chemical substance produced by the fetus and found in the fetal circulation. AFP is also found in abnormally high concentrations in most patients with primary liver cancer.

Amniocentesis—A procedure performed at 16-18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Amniotic fluid—The fluid that surrounds a developing baby during pregnancy.

Analyte—A chemical substance such as an enzyme, hormone, or protein.

Autosomal dominant—A pattern of genetic inheritance where only one abnormal gene is needed to display the trait or disease.

Autosomal recessive—A pattern of genetic inheritance where two abnormal genes are needed to display the trait or disease.

Beckwith-Wiedemann syndrome—A collection of health problems present at birth including an omphalocele, large tongue, and large body size.

Chromosome—A microscopic thread-like structure found within each cell of the body that consists of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Gastroschisis—A small defect in the abdominal wall normally located to the right of the umbilicus, and not covered by a membrane, where intestines and other organs may protrude.

Gene—A building block of inheritance, which contains the instructions for the production of a particular protein, and is made up of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Macroglossia—A large tongue.

Macrosomia—Overall large size due to overgrowth.

Maternal serum screening—A blood test offered to pregnant women usually under the age of 35, which measures analytes in the mother's blood that are present only during pregnancy, to screen for Down syndrome, trisomy 18, and neural tube defects.

Multifactorial—Describes a disease that is the product of the interaction of multiple genetic and environmental factors.

Omphalocele—A birth defect where the bowel, and sometimes the liver, protrudes through an opening in the baby's abdomen near the umbilical cord.

Polyhydramnios—A condition in which there is too much fluid around the fetus in the amniotic sac.

Thoracic cavity—The chest.

Ultrasound—An imaging technique that uses sound waves to help visualize internal structures in the body.

Ventilator—Mechanical breathing machine.

Ventral wall defect—An opening in the abdomen (ventral wall). Examples include omphalocele and gastroschisis.

cord. An omphalocele occurs when the intestines do not return, and this closure does not occur properly.

Genetic profile

In one-third of infants, an omphalocele occurs by itself, and is said to be an isolated abnormality. The cause of an isolated omphalocele is suspected to be multifactorial. Multifactorial means that many factors, both genetic and environmental, contribute to the cause. The specific genes involved, as well as the specific environmental factors are largely unknown. The chance for a couple to have

another baby with an omphalocele after they have had one with an isolated omphalocele is approximately 1 in 100 or 1%.

The remaining two-thirds of babies with an omphalocele have other birth defects, including problems with the heart (heart disease), spine (spina bifida), digestive system, urinary system, and the limbs.

Approximately 30% of babies with an omphalocele have a chromosome abnormality as the underlying cause of the omphalocele. Babies with chromosome abnormalities usually have multiple birth defects, so many babies

will have other medical problems in addition to the omphalocele. Chromosomes are structures in the center of the cell that contain our genes; our genes code for our traits, such as blood type or eye color. The normal number of chromosomes is 46; having extra or missing chromosome material is associated with health problems. Babies with an omphalocele may have an extra chromosome number 13, 18, 21, or others. An omphalocele is sometimes said to occur more often in a mother who is older. This is because the chance for a chromosome abnormality to occur increases with maternal age.

Some infants with an omphalocele have a syndrome (collection of health problems). An example is Beckwith-Wiedemann syndrome, where a baby is born larger than normal (macrosomia), has an omphalocele, and has a large tongue (macroglossia). Finally, in some families, an omphalocele has been reported to be inherited as an autosomal dominant or autosomal recessive trait. Autosomal means that males and females are equally affected. Dominant means that only one gene is necessary to produce the condition, while recessive means that two genes are necessary to have the condition. With autosomal dominant inheritance, there is a 50% chance with each pregnancy to have an affected child, while with autosomal recessive inheritance, the recurrence risk is 25%.

Demographics

Omphalocele is estimated to occur in 1 in 4,000 to 1 in 6,000 liveborns. Males are slightly more often affected than females (1.5:1).

Signs and symptoms

Anytime an infant is born with an omphalocele, a thorough physical examination is performed to determine whether the omphalocele is isolated or associated with other health problems. To determine this, various studies may be performed such as a chromosome study, which is done from a small blood sample. Since the chest cavity may be small in an infant born with an omphalocele, the baby may have underdeveloped lungs requiring breathing assistance with a ventilator (mechanical breathing machine). In 10% to 20% of infants, the sac has torn (ruptured), requiring immediate surgical repair, due to the risk of infection.

Diagnosis

During pregnancy, two different signs may cause a physician to suspect an omphalocele: increased fluid around the baby (polyhydramnios) on a fetal ultrasound and/or an abnormal maternal serum screening test showing an elevated amount of alpha-fetoprotein (AFP).

QUESTIONS TO ASK YOUR DOCTOR

- What does the term “omphalocele” mean?
- Why is omphalocele considered to be a genetic disorder?
- What factors determine the prognosis of a child born with omphalocele?
- How is omphalocele diagnosed either pre- or postnatally?

Maternal serum screening, measuring analytes present in the mother’s bloodstream only during pregnancy, is offered to pregnant women usually over the age of 35. This screening may detect various disorders such as Down syndrome, trisomy 18, and abnormalities of the spine (such as spina bifida). Other problems can give an abnormal test result, and an omphalocele is an example.

An ultrasound is often performed as the first step when a woman’s maternal serum screening is abnormal, if one has not already been performed. Omphalocele is usually identifiable on fetal ultrasound. If a woman’s fetal ultrasound showed an omphalocele or polyhydramnios, or if she had an abnormal maternal serum screening test, an amniocentesis may be offered.
